FIG. 11.—STRESS AND STRENGTH ALONG A

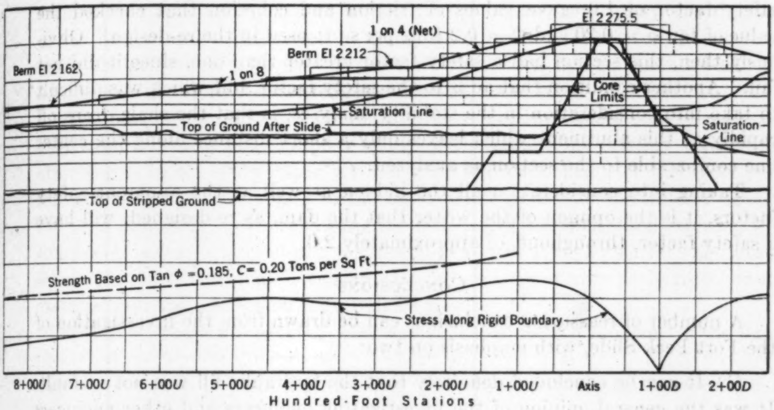
Values of cohesion and friction were determined from consolidated shear tests on undisturbed samples.

The results of these analyses on the sections prior to the slide checked against the test data further show that the failure did occur in the weathered shale and bentonite, and the results also furnish values for the coefficient of friction and cohesion which take into consideration all the variables including the excess hydrostatic pressure. In this way, a reasonable over-all value of the shearing strength of the foundation was determined for use in the re-design.

Reconstruction of the Slide Area.—In all stability analyses for the re-design of the dam in the slide area, values of $\tan \phi = 0.185$ and $C = 0.2$ tons per sq ft were used as determined from the analyses of the dam section prior to the slide. The re-design was based on two criteria established by the Board of Consultants: (1) That the factor of safety of the re-designed section should be greater than 1.5, using values of $\tan \phi = 0.185$ and $C = 0.2$ tons per sq ft; and (2) that no point in the foundation should be overstressed as determined by the elastic theory method.

Figs. 11 and 12 show the stability analysis by the Fort Peck elastic theory method for the re-designed section at Station 15+00. It will be noted in Fig. 11 that in all cases the shearing stress in the shale is well below the shearing strength at any point, and the safety factor against failure of the main dam is 1.95 (Fig. 12) and against failure of the outer slope of the berm is 1.85. The saturation line shown in Fig. 11 represents the worst condition in the upstream shell during dredging operations. As before, all the fill materials were assumed to be homogeneous and isotropic and the effect of the seepage forces was included in the analysis.

Part of Dam Not Affected by Slide.—In checking the design of the dam that was unaffected by the slide, the following criteria were established: (*a*) The factor of safety should be greater than 1.5, using the minimum shearing strength as determined from previous investigation; and (*b*) no point in the foundation should be overstressed.



Rigid Boundary, Reconstruction Plan

In analyzing the center section of the dam over the plastic clay, the results of "quick" or unconsolidated shear tests were used since they gave minimum values. No credit was taken for the increase in strength due to the consolidation in the clay strata which had occurred during construction. A maximum settlement of the embankment had already exceeded 12 ft. Most of this settlement is due to consolidation of the plastic clay. The minimum safety factor as determined for this section of the dam, therefore, is less than those that will actually exist in the completed structure. Using the minimum shear values, the minimum safety factor was found to be 1.5.

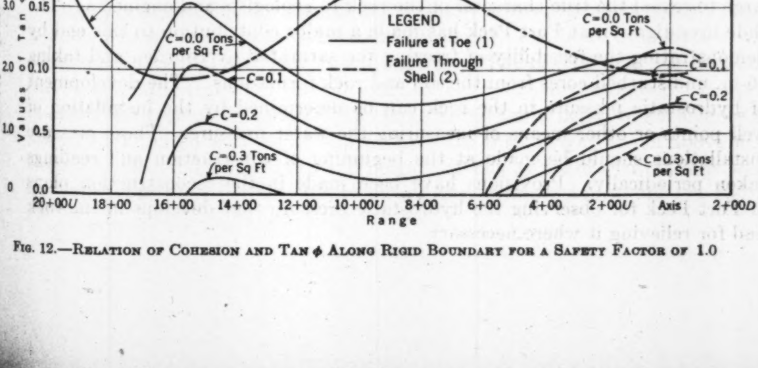


Fig. 12.—Relation of Cohesion and Tan ϕ Along Rigid Boundary for a Safety Factor of 1.0

A stability analysis was made for possible failure occurring in the shale on the west abutment at Station 85+00. The minimum safety factor was found to be 1.5. This analysis also has a hidden safety factor. An analysis of this section prior to construction of the berm, assuming that it only had a safety factor of 1.0, gave values of friction and cohesion that checked the value of $\tan \phi = 0.20$ and $C = 0.2$ tons per sq ft used in the re-design. Obviously then, this section had a safety factor greater than one, since it did not fail. Another condition that adds to the safety factor, but which was difficult to take into consideration in the stability analyses, is that the shale drops off rapidly at this abutment which leaves only a short distance along the center line comparable to the section as analyzed.

Taking into consideration all the hidden as well as the apparent safety factors, it is the opinion of the writer that the dam, as re-designed, will have a safety factor, throughout, of approximately 2.0.

CONCLUSIONS

A number of reassuring conclusions can be drawn from the investigation of the Fort Peck Slide, with emphasis on two:

(1) It can be concluded definitely that the hydraulic fill was not at fault. It was the general opinion of the investigating engineers and other engineers having an intimate knowledge of the project that the fill material performed excellently even under the most difficult circumstances existing during the slide.

(2) Furthermore, it is encouraging to note that no major changes in soil testing or methods of stability analysis were considered necessary as a result of the slide investigation, although comparison of the "static slide method" with the "elastic theory method" of stability analysis did indicate that the latter was to be preferred for the conditions encountered at Fort Peck.

The paramount question in every one's mind may be stated as follows: How can similar conditions be avoided or anticipated in the future? It is apparent, of course, since the slide did occur, that the foundation explorations and investigations, extensive as they were, did not indicate to the geologist and engineer the extent of the weathering in the shale and bentonite seams underlying this part of the dam; nor did they indicate that high hydrostatic pressures would develop in the bentonite seam due to the superimposed load of the dam. Therefore, the major problem in this connection is to always obtain representative undisturbed samples of this type of rock, sufficiently large to reveal the true character of the rock to geologists and engineers. The slide investigation at Fort Peck has made a major contribution to this end by demonstrating the feasibility of freezing the saturated overburden and taking 36-in. undisturbed cores from the soil and rock formations. The development of hydrostatic pressure in the rock can be determined by the installation of well points or other means of measuring the water pressure. These pressure installations should be made at the beginning of construction and readings taken periodically. Provisions have been made in the reconstruction plans of Fort Peck for observing the hydrostatic pressure that develops in the rock and for relieving it where necessary.

DISCUSSION

Jacob Feld,[10] **M. Am. Soc. C. E. (by letter).**—Much more can be learned from a complete description of a single failure than from many descriptions of the design and construction of stable structures. Yet, seldom is a failure made the subject of a paper. From that viewpoint, this paper is a welcome addition to the store of knowledge on the subject of soils.

The fact of the failure is common knowledge; the causes can be deduced only from a careful and complete study of the conditions existing before and after the failure. This paper gives a complete description of the tests performed on the materials used in the dam, before and after the failure. Since the tests definitely indicated strengths in excess of the computed stresses, the conclusion is drawn that sliding (or shearing failure) along subsurface bentonite seams in the "firm shale" caused the failure. Bentonite is a treacherous material and the conclusion may well be true.

However, there are several other suspicious conditions shown by the data presented by Mr. Middlebrooks. Failure occurred near Station 15, nowhere near the location of maximum loading, or maximum computed stress on the firm shale layer. Yet, there are two phenomena that occur only near Station 15, which might be a clue to the cause of the failure: (1) The bottom of the sheet piling between stations 13 and 16 is below the "top of firm shale"; and (2) the full height of fill from the original grade of 2,050 to top of dam 2,250 occurs from Station 12 to Station 16, with soil cover over the shale only 20 ft thick. These values refer to the profile along the cutoff wall, as shown in Fig. 1. Both of these facts are definite indications of possible trouble when compared to the conditions along the remainder of the profile, where the sheet piling stopped in the region designated "except firm shale" and the cushion of natural soil between the fill and the firm shale varied from 20 ft at Station 16 to 170 ft maximum at Station 64 and to a second minimum of 70 ft at Station 84.

The penetration of the sheet piling into firm shale rock makes one question whether the boring indication of firm rock is correct. If the rock could be cut by sheet piling driven through 10 ft of sandy loam and gravelly sand, and through more than 10 ft of rotten shale, then the bentonite seams that were discovered later must have been expected. The seams were probably under pressure and the firm shale was in thin layers.

The large variation in natural soil cushion always causes trouble. That is known in all foundation design and frequently has been explained as the cause for differential settlements in buildings. The natural soil was certainly less consolidated (further from the critical density) than the prepared mixture in either the core or the shells. The large variation in depth of subsidence at stations 20 and 60 is much less apparent if the total height of soil above firm shale is considered. Although the heights of fills at these two stations were the same, the total depths of rock below the ultimate top of fill are 250 ft and 370 ft, of which 230 ft is the additional fill. At the fill height of 150 ft, the total depths to rock were 170 ft and 290 ft; the corresponding subsidences (as given in Fig. 7) are 3 ft and 6 ft.

---

[10] Cons. Engr., New York, N. Y.

The tests of the shell materials show a high shear strength; this corresponds to a small value of shear strain at failure. The writer believes that both the core and the shells were too rigid to take up the differential subsidence or settlement without failure. Once the shear cracks had developed in the body of the fill, lateral pressure against the upstream shell, founded as it was on a water-bearing seamy rock, caused outward movement.

The effect of the surcharge load on the liquid bentonite in the seams was to increase the uplift pressure on the base of the fill. The tendency for the pressure to be relieved by escape of the liquid was nullified by the fact that bentonite does not give up its water easily and by the compression of the seams under the added load. The seamy shale might have been strong enough when not compressed and also when compressed with a sufficiently large layer of porous cover. The high hydrostatic pressure in the shale was noted in the core holes (see Table 1 and supporting text). The actual loading on the shale near Station 15 was much more than the weight of the material directly above it because of the lower subsidence at this station as compared to the remainder of the fill. Such a condition explains the findings for a hole in the fill near Station 14 + 75, down to natural surface; it is similar to the open crack which develops in a wall founded on varying depths of unconsolidated soil or in a wall founded partly on rock and partly on soil.

In the opinion of the writer, this failure is another example to prove the correctness of the rule that unequal settlement is more to be guarded against than overload. Excessive settlement did not contribute to the failure—quite the contrary. Lack of settlement due to the thin cushion, and probably also the high resistance of the relatively sudden slope in the right-hand bank, caused internal failure, and the earth pressure on the shell did the rest. To complete the paper, it is hoped that Mr. Middlebrooks will define "factor of safety" in the closing discussion.

To follow customary practice in structures, the dam should have been built in one of two ways: (1) Vertical cleavage joints, with proper shear dowels, at about stations 20 and 85; and (2) construction of the dam between stations 20 and 85 first, closing the ends after the consolidation and subsidence were substantially complete. A combination of the two methods can be developed.

The reconstructed area that failed will not be exposed to the same transfer of load, nor the same shearing failure, since the main part has substantially reached its final position. In the writer's opinion, the failure was caused by the "erection" stresses due to differential vertical shrinkage, and, once that state has been overcome, the structure as designed by either the elastic theory method or the static slide method is stable. The paper is additionally valuable in outlining in so clear a fashion all the factors requiring investigation in the design of large earth dams.

Joel D. Justin,[11] M. Am. Soc. C. E. (by letter).—There is only one good thing about a slide such as occurred at Fort Peck. If it is thoroughly investigated and studied, the engineering profession is thereby better equipped to prevent similar slides in the future. Therefore, Mr. Middlebrooks' paper is worthy of careful study by all engineers interested in the design and construction of earth dams. It should help to clear away the misconceptions of many engineers who have not had the opportunity to study the investigation that followed. Thus, one engineer recently told the writer that he was opposed to using a hydraulic-fill dam at a certain location because hydraulic-fill dams had a habit of sliding upstream!

---

[11] Cons. Engr., Philadelphia, Pa.

The investigation of the Fort Peck Slide was undoubtedly the most thorough and extensive that has been made in connection with any earth-dam slide during construction. The importance and size of the structure and the investment involved justified the extent to which the investigation was carried. Any one who takes the trouble to study the complete record of the investigations[12] thoroughly will reach the conclusion that the cause of the slide was insufficient shear strength in the foundation to resist the stresses imposed by the dam as originally designed at the section where failure occurred.

The main dam is approximately 10,000 ft long, but the slide was limited to the upstream part of the dam, approximately between stations 4 and 30. The investigation gave no indication that the foundation under the downstream part of the dam between stations 4 and 30 was any better than the foundation under the upstream part of the dam in this section, but there was no movement in the downstream part of the dam at any point. In this connection, it is significant to note that, whereas the average upstream slope in the section where the slide took place averaged 1 on 4, the slope of the downstream face in the same section averaged 1 on 8.5. It is also significant that immediately north of the slide area there was an extensive upstream berm at El. 2,112 extending from Station 30 to Station 75 (see Fig. 13).

The flatter downstream slope resulted in lower intensity of shear stress both in the foundation and at the base of the dam. Similarly on the upstream side, the berm north of Station 30 resulted in lower intensity of shear stress in the foundation just north of Station 30, where there was no movement, than in the foundation just to the south of Station 30 where the slide took place.

Thus from the foregoing it is evident that at the section where the slide took place, not only was the foundation weaker, as shown by Mr. Middlebrooks, but also the unit shearing stresses in the foundation were higher than in the adjoining section.

As a result of the investigations and studies conducted after the slide, and in accordance with the decisions of the Board of Consultants appointed for the purpose, the design was modified and the sections shown in Fig. 14 were adopted and executed for the reconstruction.[12]

Hydraulic-fill methods were used in placing the larger part of the additional shell material within the slide area and also for the extensive additional upstream berm throughout the remainder of the dam. The new core (which was a highly impervious glacial till from the north abutment) and the topping off of the dam, were constructed by rolled-fill methods. The upper part of the

REDESIGNED AND RECONSTRUCTED AFTER THE SLIDE downstream face was steepened to 1 on 4, as indicated in Fig. 14, and the material thus salvaged was used in topping off the shell.

In effect, the slide provided a life-sized laboratory test for determining the shear resistance of the foundation. Consequently, the determination of the factor of safety for the redesigned section may be accepted with considerable confidence.

WILLIAM GERIG,[13] M. AM. SOC. C. E. (by letter).—The excellent paper by Mr. Middlebrooks has covered the subject of the Fort Peck slide very well. In an effort to show the class of material placed in the dam as well as in the foundation, the author shows that much work in securing borings and other data was done in a thorough manner.

The writer has never experienced a case in which a "flow failure" has occurred in the dredge material. One who is familiar with dredges should know that sand handled by a dredge has practically all the clays and other sliding material removed, and placed on the core or washed off the dam, so that the particles of sand are compelled to slide on themselves, and, therefore, must have a high friction content. Dredged sand usually is a very closely packed material. As previously stated, the writer has never encountered a "flow failure" in dredged sand.

The material moved so far at Fort Peck, not because of a reduction in the strength of the material in the dam, but because of a reduction in strength in the foundation shale. The failure in the hydraulic fill, such as in a dam, is generally caused by an improper foundation, and sometimes by inferior material that is placed in the dam at improper slopes. The writer has never experienced such material as "partial liquefaction." When he signed the Report of the Board of Consultants,[14] he had in mind that the foundation material contained some clay, which might have been in a "state of liquefaction." In fact, when the word was first used in the Report, he did not know what it meant; but after the word was defined as being similar to what is usually called "quicksand," he thought the clays might flow.

In the Zanesville (Ohio) District (U. S. Engineer Office), for example, a part of a river was unwatered, and it was found that the material in the bed consisted of pebbles, small boulders, and sand, and that this was in a state similar to "quicksand." One cannot imagine that these boulders, in this condition, would liquefy in the sense that Webster defines it. The writer, therefore, fully indorses Mr. Middlebrooks' conception that the material in any part of the dam was not liquefied, and that the slide at Fort Peck Dam occurred in the foundation.

The conditions were quite similar (as far as could be seen) on both abutments, except that the downstream slope was 1 on 10, whereas that of the upstream was designed for 1 on 4.5 at the east abutment. The design was similar at the west abutment. There was little evidence of disintegrated shale at this abutment, however, because evidently there was a stronger current during high water, and this current had carried off the disintegrated shale. The west abutment, furthermore, was composed of a larger percentage of more or less firm glacial till.

---

[13] Cons. Engr., Arkadelphia, Ark.

[14] Report on the Slide on a Part of the Upstream Face of the Fort Peck Dam, War Dept., Corps of Engrs., U. S. Army, 1939.

Mr. Middlebrooks also mentions the 1-on-3 construction slopes in the closure of the dam where the river was used as an outlet for surplus water. This slope was not found stable in the test dams and was used only in the river section proper, so that when the closure was made the quantity of material required for the closure would be less than on a flatter section. When it was definitely decided that this slope was too steep, it was changed to about 1 on 4.5 and gave no more trouble.

If the failure on the east end of the dam was due to anything except a poor foundation (and probably the increased slope on the upstream side when the location of the dam was changed), it would have been evident on the downstream side. The bentonite seams were found in the tunnels, and they were not discharging a large quantity of water; in fact, there was no trouble with water in these tunnels. If the water in the bentonite seams were a contributing cause of the slide, it would have been shown in these seams, where they extended farther than the downstream side of the dam.

The author submits a statement showing the large number of borings and other data that were obtained prior to the construction of the dam and also the large total number that were obtained. Many of these data were duplicated after the slide occurred and were obtained chiefly as a check. The greatest possible care was taken to obtain the data correctly, and tests were carefully made and studied for this purpose. Often the data obtained by means of tests in a laboratory are not satisfactory. To illustrate: Obtaining the friction through various sizes of smooth pipe (approximately 8 in., 12 in., 20 in., and 30 in. in diameter), the frictional resistance per hundred feet was found to be different for the different sizes of pipe, although the velocities were kept the same in all sizes. This statement is inserted to show that entire dependence cannot always be given to the results of laboratory tests. This is true in many of the tests made in soil mechanics, and for that reason and others the writer views with doubt some of the results in soil mechanics obtained in this manner. Earth dams were built many years ago and some are still standing, although the theory of soil mechanics was not known to those builders.

ALFRED J. RYAN,[15] ASSOC. M. AM. SOC. C. E. (by letter).—The only true test of any method of analysis of earth embankments is to apply that method to the failure of an actual structure. Such an application is dependent upon knowledge of all of the facts pertaining to the failure. Mr. Middlebrooks' frank and complete description of the failure, and of the apparent reasons for the failure, at Fort Peck Dam is a valuable contribution to this phase of engineering.

The conclusion that the failure was the result of a weakened foundation seems sound beyond any reasonable doubt. If it is true that the static slide method of analysis, properly applied, would not indicate this failure, it is a matter of grave concern to those who have analyzed existing structures by that method. Any method of analysis, when applied to an embankment composed of more than one material, has some doubtful features. The static slide method is no exception, but it is no less applicable to the plastic flow condition than to any other condition.

---

[15] (Crocker & Ryan), Denver, Colo.

The essential difference between the "elastic state" and the "plastic state" of soil is the existence of excessive hydrostatic pressure of the fluid contained in the voids of the latter. The fluid consists of water or air, or a mixture of the two. When a load is applied to a soil that has not been sufficiently consolidated, the soil particles attempt to adjust themselves to this load. This requires a reduction in the volume of voids. In a soil that resists drainage, the fluid in the voids cannot escape quickly enough to allow this reduction and part of the load must be carried by hydrostatic pressure of the fluid. It is commonly called "pore pressure" and cannot produce friction. As the fluid escapes, the volume of voids and the intensity of the pore pressure are reduced. The rate of reduction is a function of the permeability of the soil and of the distance to a drainage face. That part of the load not carried by the fluid (that is, the total load minus the pore pressure) is carried by the grain-to-grain contact of the soil particles and does produce friction. Therefore, the static slide method is adapted to a plastic condition by making the proper corrections for pore pressure. Methods of evaluating this pressure have been developed by Karl Terzaghi,[16] M. Am. Soc. C. E., and by J. H. A. Brahtz.[17]

The basic concept of the static slide method is that of an instantaneous failure along the entire sliding surface. Observed failures of both models and actual embankments have proved that this is not the case. Instead, the failure is progressive and the failure surface indicated by the analysis represents the approximate limit of this progression. A careful check as to the effect of this inconsistency reveals that the summation of the sliding forces and of the resistance can be represented by the basic concept as long as stability is maintained. Consequently, the fact that the conditions of an earth embankment are such that any failure will obviously be progressive does not exclude this method of analysis.

The writer has made a static slide analysis of the section with pore pressures computed by the method developed by Professor Terzaghi. The analysis was made at Station 15+00, as shown in Fig. 8, and was based upon information given by the author and in the report of the slide.[18] The consolidation characteristics of the soils were taken from the results of tests of representative samples of the various materials as shown in the report. The sample of foundation material was from the Merriman Drift and was classified as undisturbed weathered shale. The core sample was from Hole C–7. The shell material was assumed to be consolidated to the imposed load and to have no pore pressure. Due to lack of sufficient information, a check of the computed pore pressures by Mr. Brahtz' method was impossible. However, approximate agreement of these pressures with those shown in Fig. 1 was considered an adequate check. The computations indicated pore pressures in the weathered shale of sufficient intensity to make the shale, as well as the bentonite, susceptible to failure.

[18] Report on the Slide of a Portion of the Upstream Face of the Fort Peck Dam, Corps of Engrs., U. S. Army.

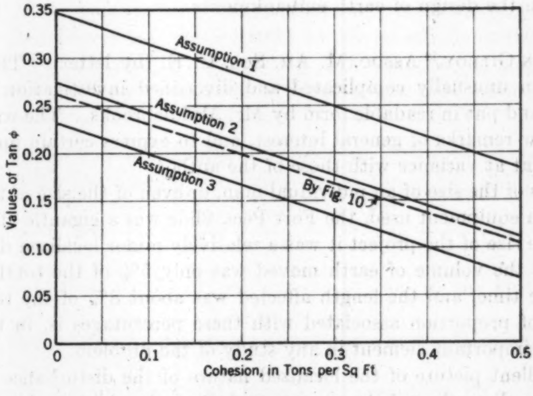

FIG. 15.—STRENGTH REQUIRED FOR STABILITY

Computations of the pore pressures in the core were complicated by the fact that the location and extent of the sand lenses were not known. Analyses were made for three assumptions regarding the effect of these lenses: (1) Neglecting the effect of the lenses; (2) assuming lenses such as to provide a 50% decrease in the distance between drainage faces; and (3) assuming lenses such that the pore pressures were completely dissipated at the time of the failure. The first and third assumptions were obviously used to establish limits and the second to indicate the intermediate trend. Comparison of computed consolidations along the center line of the core with those given in Fig. 5 indicate that the true condition lies somewhere between the first and second assumptions. Results of an analysis based upon the second assumption would be liberal instead of conservative.

Results of the analyses are shown in Fig. 15. The requirements for stability are slightly higher for the second assumption than those found by the author by the elastic theory method. In the writer's experience, this has usually been the case when comparing the results of the two methods. The author states that a static slide analysis will not indicate failure if a value of tan $\phi = 0.6$ is used for the core material. But this analysis does indicate failure. With the exception of the pore pressures, the analysis was based entirely upon information given by the author or in the report, including the value of tan $\phi = 0.6$ for the core material. Only two differences can exist: (1) The generalization of using the values of one representative sample for each material; and (2) the pore pressures. All embankment analyses are based upon a degree of generalization, so any difference from that source should be small enough to be negligible. Apparently then, the adaptation of the static slide method of analysis to this type of dam is dependent upon the correct application of the pore pressures, and these pressures were the only conditions not fully covered by the author.

Therefore, it is felt that if more complete information along this line were included in the concluding discussion, it would be of definite value to all of those interested in the design of earth embankments.

GLENNON GILBOY,[19] ASSOC. M. AM. SOC. C. E. (by letter).—The principal results of an unusually complicated and diversified investigation have been condensed and put in readable form by Mr. Middlebrooks. The writer wishes to add a few remarks of general interest, and to express certain opinions that are somewhat at variance with those of the author.

In terms of the size of an individual man, or even of the size of the massive construction equipment used, the Fort Peck Slide was a gigantic affair; but in terms of the size of the project it was a relatively minor localized disturbance. Specifically, the volume of earth moved was only 5% of the total volume in place at the time, and the length affected was about 8% of the total length. The sense of proportion associated with these percentages is, in the writer's opinion, an important element in any study of the problem.

An excellent picture of the localized nature of the disturbance is given in Fig. 2. The distortion of the upstream shell at the right (westerly) edge of the break shows clearly that the dam at this point had sufficient reserve strength to offer effective resistance against further propagation of the movement. The cross section here was no stronger than that in the slide area. Hence arises the logical inference that the dam itself was stable under the existing conditions, and that a weakness of the foundation, strictly localized in the vicinity of the right abutment, must have been responsible for the movement.

Fig. 1 illustrates the manner in which the foundation near the right abutment differed materially from that in the major part of the valley. The shale surface rises to a flat bench at a relatively shallow elevation, extending approximately from Station 13 to Station 19. A considerable depth of weathering is shown and the depth of penetration of the sheet piling indicates low resistance in the surface shale. Furthermore, the shale is interspersed with seams of bentonite, which tend to decrease its shearing resistance, especially in a horizontal direction.

Mr. Middlebrooks also mentions the intake channel, 800 ft upstream from the toe, and cut into the shale to El. 2,030. A significant detail in this connection is that the channel was cut approximately parallel to the dam from the intake structure, Station 11, out to Station 19, from which it veered sharply upstream.

Thus it is clear that a substantial length of the dam near the right abutment rested on a shelf of weathered shale and bentonite which, on account of its shallow depth, was subjected to the full intensity of horizontal shear induced by the embankment, and which was horizontally unsupported as a result of the channel excavation.

---

[19] Cons. Engr., Falls Church, Va.

It is the writer's belief that the shearing strength of the material composing this shelf, though undoubtedly increasing somewhat under the weight of the dam, did not increase fast enough to keep pace with the increasing horizontal shear; that the margin of safety was thus decreased as the height of the dam increased; that the balance point was reached when there was still about 25 ft to go; and that movement was initiated by an essentially horizontal shear failure of the shelf material in the direction of its unsupported face.

The observed facts were consistent with this hypothesis. Among the more significant are:

(1) The failure was not sudden, but gradual. Distortions visible to the unaided eye were noted more than three hours before the slide took place. How much strain had developed previously it is impossible to say; but a considerable amount could have gone undetected due to the very nature of the operation.

(2) The distortions were maximal between Station 15 and Station 17, the precise center of the critical zone previously described.

(3) The first indication of the rapid final phase of the slide was a settling of the core pool in this zone.

(4) Initially, the upstream shell moved out practically all at once, like a huge gate hinged at the abutment.

(5) Subsequent investigations showed masses of weathered shale to be partially or wholly absent from their positions as determined by earlier borings.

So much for the initial phase. It should be noted here that the foregoing concept is the writer's personal explanation, and that, although the Board of Consultants agreed unanimously on the weathered shale zone as the source of the trouble, the detailed concepts of the individual members may differ materially from that presented here.

As to the progress of the slide after the initial failure, no unanimity of opinion was obtainable, and the Board was obliged to leave the question undecided in its final report. Since the writer's opinion on this point does not coincide with that expressed by the author, an explanation of the reasoning behind it seems indicated.

The upstream movement of material was truly remarkable. The intake channel, 800 ft upstream from the toe and 500 ft wide, was completely filled, to depths as great as 40 ft. Fanning out of material toward the center of the valley was on a comparable scale. Intact masses of the upstream shell moved more than a thousand feet from their original positions. The author's explanation of this extensive movement is that "liquefaction" took place in the weathered shale and bentonite zone, due to trapped water. This is equivalent to stating that the shearing strength of this zone reached a maximum at the instant of initial failure, and decreased to a considerably lower value after the peak point was passed. The writer does not dispute the probability of such reduction in shearing strength, but submits that by itself it is not sufficient to account for the observed behavior of the slide.

Suppose the dam had been constructed by rolled-fill methods. Horizontal base shears would have existed, of course. Suppose further that the dimensions of the rolled-fill structure and its rate of construction had been such as to bring about a balance of shearing stress and shearing strength in the weathered foundation zone when the dam was within 25 ft of the top. Shear failure in the foundation would have taken place. Reduction of shearing strength beyond the peak point would have exaggerated the movement. Considerable damage would have resulted, and expensive repairs would have been required. However it is inconceivable, to the writer's mind at least, that the rolled-fill material would have moved to anything like the extent observed in the actual slide. Outward movement of the toe, severe slumping in the main body of the dam, cracking, fissuring, faulting, all these things the writer can visualize; but nothing like an upstream movement of more than a thousand feet.

If this visualization is sound, it follows that the progress of the actual slide was intimately associated with the peculiarities of hydraulic-fill construction. Among these are: Complete saturation of the central part of the dam, with an excess of water on top; segregation of progressively finer materials from the outer slopes toward the core; and no artificial compaction. When construction is progressing normally, these items are merely part of the program; but if a disturbance occurs, they can unleash latent forces within the body of the dam which will tend to exaggerate the results of the disturbance.

Consider the effect of the core pool alone. If a shear failure of the foundation occurs, removal of support from the core will cause it to slump. A rolled-fill core would slump under similar circumstances; but when a hydraulic core slumps, the water of the core pool piles up at the low spot and produces an additional push on top of the core, thereby exaggerating the movement of the slide. This action will continue until the shell is fissured, whereupon the accumulated pool water will rush out through the fissures, carrying masses o core and shell material with it.

Segregation of fine, saturated, sandy material in the vicinity of the core—in the section of the dam often termed the "transition zone"—is another potential source of hazard. The coarser parts of the shell are inherently stable, or can be made so by artificial compaction; but the transition zone, half in and half out of water, is difficult to treat. A violent disturbance will tend to produce a temporary "quick" or "liquefied" condition in this zone, with a consequent increase of internal pressure and a further tendency to exaggerate the effect of the disturbance.

The writer submits that both the foregoing influences are present in any hydraulic-fill dam; that they were present in the Fort Peck Dam; that the initial disturbance due to foundation failure was violent enough to bring them fully into play; and that they were primarily responsible for the great distance covered by the slide after the initial failure.

The author dismisses the possibility of liquefaction of the shell on the ground that subsequent tests (Fig. 6) showed that the shell was denser than the critical value obtained for most of the samples tested. The writer agrees that most of the shell, certainly the outer parts, behaved very well; but this is no proof that liquefaction of the transition zone did not take place. On the contrary, at the time of the writer's first inspection, ten days after the slide, much of the surface material in the slide zone, especially the fine sand, was still in a "quick" condition, and it is difficult to imagine that it was not so during the occurrence of the slide. The amount of material which liquefied might have been small in comparison with the volume of the slide, yet might have played a very important rôle in keeping the more stable masses on the move.

As far as the critical density tests are concerned, it will be noted that the density of the fill coincides closely with the "minimum critical density" curve of Fig. 6. This means that the margin of safety was not very great. Although it is true, as the author states, that sands looser than critical may exhibit some residual shearing strength when disturbed, the writer believes that the nature and violence of the disturbance are of great importance, and that saturated sands somewhat denser than critical may, if sufficiently disturbed, pass through a temporary condition of liquefaction before attaining a new condition of equilibrium. Therefore, the writer contends that the critical density tests do not prove the absence of liquefaction; and that the balance of other evidence is strongly in favor of the view that some liquefaction took place, especially in the transition zone, and assisted in the movement of the slide.

In view of these considerations, the writer is now of the opinion that his method for computing shell stability does not contain as great a hidden factor of safety as might at first glance be expected. To provide absolute safety under all conditions, the parts of the shells which are inherently stable when deposited, or can be made so by artificial compaction, should be strong enough to withstand possible liquid pressure from the transition zone which might be produced by subsequent disturbances. While this may seem an unnecessarily severe criterion, it must be remembered that as improvements in design methods permit increasing economies in cross section, the influences of previously negligible factors become increasingly important.

In conclusion, the writer wishes to endorse the views of the author concerning the importance of thorough quantitative investigations of the properties of weak rocks such as those encountered at Fort Peck. These materials fall into a sort of twilight zone, where soil mechanics ends and geology begins, and the combined efforts of workers in both subjects should go far toward reducing the uncertainties now existing in this field.

FRANK E. FAHLQUIST,[20] ASSOC. M. AM. SOC. C. E. (by letter).—The engineering profession is indebted to Mr. Middlebrooks for his thorough analysis of the causes and behavior of the Fort Peck Dam slide. To the writer, at least, the crux of the entire problem is indicated in the author's discussion of the rock foundations, as stated under the heading "Test and Analysis Prior to Slide: Slides on Shale" (first thirteen lines). Also of particular interest are the first ten lines of the author's concluding paragraph.

---

[20] Senior Geologist, U. S. Engr. Office, Providence, R. I.

During the summer of 1931, the writer had an opportunity to study the geology of several potential dam sites in the Missouri River Valley of Montana. Although the time available for this work was limited, and the area covered was great, sufficient information was obtained to indicate that, before any final selection of sites, designs, or constructions could be made, consideration should be given to several important problems bearing on the geology of the Missouri River Valley and the design and construction of dams. These geologic problems have not been adequately described in the paper nor in any other accounts of the Fort Peck Dam slide that have come to the writer's attention.

The Missouri River Valley, from the North Dakota state boundary line to Great Falls, Mont., is formed in an alternating series of inclined shale and sandstone formations. These rocks are of Cretaceous age and, therefore, in a geologic sense, are comparatively young. As a result, but chiefly because there has been only a slight burden of overlying sediments, subsequently removed by erosion, these rocks have behavior characteristics that are not ordinarily a part of rock formations found in other parts of the United States. The several sandstone members of this sedimentary series, throughout the eastern half of the valley, in general, are poorly cemented and friable. The shale members (that at the Fort Peck Dam being known as "Bearpaw" shale) are only partly consolidated or indurated. However, where this formation occurs buried beneath an overburden of soil or water, and, further, where it has not been affected by any geologic disturbances, the rock is firm and stable. These shales, however, have two undesirable characteristics or properties: (1) They contain stratifications of bentonite ranging from a fraction of an inch to several inches in thickness, and (2) when uncovered and exposed to the air, they readily disintegrate or slack into innumerable small pieces.

In his reconnaissance of the valley, the writer was impressed at the evidences of landslides of both recent and old age. Several areas were noted where large masses of shale and sandstone had broken off of the inner valley cliffs and slid on to the valley bottom. Some of these landslides were pronounced and easily identified, whereas others, being eroded and probably of greater age, were difficult to recognize. At one dam site, located at a considerable distance above the Fort Peck Dam, but within the reservoir, landslide activity had extended over a large area, causing the writer to recommend elimination of the site from further consideration.

With these extraordinary geologic conditions in mind, the writer, in submitting his report,[21] outlined several broad concepts that should be considered in the investigation, design, and construction of any dams located in the Missouri River Valley:

(1) That the air-slacking shale presented a special construction problem in rock excavation work. It was not anticipated, however, that this property would create any serious difficulties, as the condition could be easily remedied by forced applications of portland cement grout on freshly excavated rock surfaces. Actually, in the construction of the Fort Peck Dam, asphalt was used, which is equally suitable. In addition, the ease with which the shale

---

[21] Report to the U. S. Engineers, Kansas City District, Kansas City, Mo., November, 1931.

disintegrated precluded its use as riprap or in rock fills. Obtaining more suitable and durable rock from distant igneous rock areas was recommended. Actually, hard, durable boulders were shipped in to the site from a remote area.

(2) That the occurrence of bentonite in the shale formation and evidence of landslide activity presented the most serious problem. The writer judged that the bentonite stratifications could be, and probably were, the cause of many of the landslide effects. Because the Bearpaw formation extends over such a large area, the writer was led to report that:

> (*a*) Landslide activity should be investigated at any sites finally selected;
>
> (*b*) If any landslide blocks of large proportions were found to occur at any of the selected sites, the question of further study and construction or abandonment was a matter of cost versus benefits, compared with other sites; and
>
> (*c*) In the case of all dams in the valley, particular care should be exercised in foundation and abutment constructions. If surface and subsurface investigations revealed occurrence of landslides or other disturbance in the foundation rock, this condition, together with occurrence of bentonite stratifications, would be serious, and probably would warrant excavation and removal of all rock affected by these deformations. This precautionary measure would be necessary to assure founding the dam in the abutment areas on undisturbed bedrock.

The author's discussion of the rock foundations, under the heading "Tests and Analysis Prior to Slide: Slides on Shale" (particularly his description of conditions disclosed by later investigation), leads the writer to believe that the 30-ft thick zone of blocky weathered shale that gradually passes into a subfirm and firm shale is quite likely an eroded remnant of an old landslide block. The observations as disclosed by detailed investigations tally exactly with conditions observed by the writer in the field. The author's conclusion that the solution to similar problems may be found by obtaining representative undisturbed samples does not go far enough. The very first essential in a problem of this kind, or in any foundation or abutment problem, is an understanding of the geologic history of the area or region. Such an understanding, no matter how meager the evidence is at first, will help one to formulate a method of attack for accumulating more pertinent information and to separate the more serious and important problems from those of less importance. Undisturbed samples are fine and necessary, as is also the analysis of stress and strain, but the writer can easily imagine cases in which any amount of undisturbed sampling and mathematical analysis could not fully develop a complete geologic picture. For example, consider the blocky weathered condition described by the author. In this case there is a disrupted mass of rock, a shale which disintegrates and slacks readily, which contains stratifications of bentonite, and which, when weathered and wet at the surface, forms a sticky and slippery mass of soil. When such conditions are recognized, the only adequate exploration to confirm or disprove preliminary geologic conceptions is twofold: (1) A few well-selected and carefully executed borings to outline the extent of such geologic conditions, and (2) real life-size excavations to explore the condition fully, in area and in depth. When this exploratory work is completed, all testing done, and all factors of safety computed, one should bear in mind that there may still be some worse condition not yet disclosed, and then one should consider carefully whether it would not be best to remove the entire questionable mass and build on undisturbed material.

Irving B. Crosby,[22] **Affiliate Am. Soc. C. E.** (by letter).—The causes of the Fort Peck slide have been discussed by Mr. Middlebrooks in his very useful paper, and he has shown that the slide was due to weakness in the foundation shale and not to any weakness in the dam itself. The writer believes, however, that certain geologic factors have not been brought out by the author and that an erroneous impression has been given by some of the statements.

The Board of Consultants unanimously agreed that the slide "was due to the fact that the shearing resistance of the weathered shale and bentonite seams in the foundation was insufficient to withstand the shearing force to which the foundation was subjected,"[23] but as to the relative importance of the various factors the Board could not reach agreement. The writer is solely responsible for the following ideas, some of which may be at variance with those of other members of the Board:

The Bearpaw shale in the vicinity of Fort Peck Dam has been intersected by numerous faults or fractures on which movement has taken place. Many of these faults were due to deep-seated causes, but some of them were caused by landslides in the bluffs of the Missouri Valley at a time when the river was flowing at a lower level. The principal results of the faults were the production of numerous planes of weakness and of channels for ground-water movement. Study of the numerous boring cores and records made after the slide indicated that there was horizontal movement on a bed of bentonite and that this plane of movement reached the surface largely through weathered shale. The writer believes that the bentonite beds and faults played a very important part in causing this and previous slides.

Mr. Middlebrooks has described the hydrostatic pressure found in many borings in the shale and has ascribed to this pressure an important part in causing the slide. He states that prior to the construction of the dam the bentonite seams were covered by only a shallow overburden, that they had expanded and taken up water, and that then the superimposed load of the dam caused high hydrostatic pressures in the bentonite, which facilitated the slide. No such condition (water taken up by the bentonite) existed, however, in the case of the older slides in the bluffs. In those slides the bentonite was still under a thick load, and it did not have opportunity to take up water and expand. These slides were due to undercutting of the bluff by the river with consequent indirect and very gradual overloading. Similar slides on a small scale have occurred in the banks of the reservoir since the water was raised and lowered, and in every case observed by the writer there was a bed of bentonite. Similar slides occurred at Snake Butte, Mont., associated with beds of bentonite in the shale, but in this case the peculiar situation of thin overburden and sudden overload assumed by the author did not exist and yet slides occurred.

---

[22] Cons. Eng. Geologist, Boston, Mass.

[23] "Report on the Slide of a Portion of the Upstream Face of the Fort Peck Dam," Corps of Engrs., U. S. Army, July, 1939, p. 8.

The writer believes that the water squeezed out of the shale in the various borings came largely from the intricate network of fractures in the shale and to only a small extent from the pores of the shale and bentonite, and that "liquefaction" of the bentonite previous to the slide did not exist. Once movement occurred, however, water from the fractures may have been mixed with the bentonite and facilitated the extent of movement. The presence of flat bentonite beds and of fault planes inclined toward the valley provided planes of low resistance on which movement occurred when the superimposed load became sufficiently great.

Mr. Middlebrooks concludes that the best means of avoiding similar slides in the future "is to always obtain representative undisturbed samples of this type of rock, sufficiently large to reveal the true character of the rock tc geologists and engineers." Numerous undisturbed samples of this shale and bentonite were taken, however, and numerous tests were made on them prior to the slide; but the true condition of the shale was not understood and the slide was not foreseen.

This writer doubts that more and larger samples would have disclosed the dangerous foundation condition unless the geologic history of the region had been correctly interpreted first. The history of past slides is written physiographically on the face of the bluffs. Nature has been conducting large-scale tests on the shale, over a long period of time, in a manner that cannot be duplicated in the laboratory. Correct understanding of these natural tests will often reveal what laboratory tests fail to show. The tests, by nature, in the bluffs have shown that the bentonite is the weakest natural material in this region and that slides frequently occur on it. Correct interpretation of the physiography and stratigraphy shows that great masses of shale have slid from their original positions and that the shale in the bluffs may be intersected by innumerable zones of weakness.

With the geologic and physiographic history of the region correctly interpreted, the possibility that a dangerous situation may exist becomes apparent. Then clues that may have been overlooked would be recognized and warning given, and the actual conditions could be disclosed by special investigations. Had the true conditions been understood, the dam could have been designed to meet those conditions safely.

T. A. Middlebrooks,[24] Assoc. M. Am. Soc. C. E. (by letter).—Mr. Feld declares that "large variation in natural soil cushion always causes trouble." The writer cannot agree with this statement. If trouble was to be experienced from a wide variation in the thickness of the natural overburden, the slide should have occurred on the left abutment instead of the right abutment. Between stations 12+00 and 19+00, the thickness varied from zero to about 25 ft, a change of approximately 3.5 ft in 100 ft; whereas, between stations 77 and 84, the thickness varied from 100 ft to 10 ft, a change of approximately 13.0 ft in 100 ft. It is evident, therefore, that this change had nothing to do with the failure. The writer has investigated numerous earth slides and has found none that could be remotely attributed to a change in thickness of the overburden in the manner described by Mr. Feld.

---

[24] Prin. Engr., Corps of Engrs., War Dept., Soil Mechanics Section, Washington, D. C.

Mr. Feld's conclusion that the fill was too rigid to take up the differential settlement can scarcely be substantiated. Actually, differential settlement between stations 10+00 and 20+00 was quite small—approximately 0.25 ft (3 in.) in 100 ft. Such a small differential movement could not cause shear failure in either the sand shells or the core.

He concludes correctly that the surcharge load increased the hydrostatic pressure in the shale and caused uplift (excess hydrostatic) pressures in the base. The fact that the surcharge load, as pointed out by the writer, was the sole cause of the excess hydrostatic pressure in the shale has been definitely proved by further investigation since the slide.

The writer is at a loss to understand how Mr. Feld would increase the stability of the structure by the use of "Vertical cleavage joints, with proper shear dowels," and the "construction of the dam between stations 20 and 85 first." It is customary practice to place cleavage joints and shear dowels in concrete structures. However, their use in the Fort Peck Dam would have served no useful purpose and would have been entirely impracticable to construct. Observations on the excess hydrostatic pressure in the shale, since the slide, have shown conclusively that any reasonable extension of the construction period would not have materially increased the strength of the shale and bentonite, or reduced the excess hydrostatic pressure.

In Mr. Feld's closing paragraph he has evidently confused stress with strength in his reference to "'erection' stresses." The stress in a given earth structure will be practically the same directly upon completion as it will after the shrinkage in the dam and settlement in the foundation have been taken up. The greatest variable is the strength of materials involved, which reaches a maximum only when the materials are 100% consolidated.

The writer was pleased to have Mr. Justin's discussion and his agreement as to the primary cause of the slide. As Mr. Justin states, considerable confidence can be placed in the redesigned section since the slide was used as a full-scale test for the determination of the over-all strength of the materials involved.

Mr. Gerig's statements concerning the stability of dredged sand, and his conclusion that the sand shell did not flow or liquefy, should be noted carefully. Since Mr. Gerig's experience checks with the conclusions drawn from tests conducted on the shell material and observations of the undisturbed cores, it can be concluded, without question, that the sand shell did not flow or liquefy.

The writer agrees fully with Mr. Gerig's conclusion that "entire dependence cannot always be given to the results of laboratory tests." However, laboratory tests are essential where there is no past experience upon which to rely, and they are a necessity to the practical engineer in all other cases to supplement his judgment and experience.

Mr. Ryan's clear description of the action of excess hydrostatic pressure in the voids of a soil is most interesting. The writer agrees that for most cases the static slide method will give satisfactory results provided the distribution and amount of excess hydrostatic pressure and the reduction in strength due to progressive movement are known. An investigation reported in 1941 by the U. S. Waterways Experiment Station (Engineer Department)[25] shows that, with the proper determination of the excess hydrostatic pressure and remolding effect due to progressive movement during construction, the circular slide method will give reasonable results.

Evidently Mr. Ryan found in his stability analysis (Fig. 15) the same thing as the author—namely, that by proper manipulation of the shearing strength of the core he could get the two methods to check. It is well to emphasize that for a correct analysis by any method the distribution and amount of excess hydrostatic pressure and the decrease in strength due to progressive movement must be known. In the redesign of the section these factors were taken into consideration by using over-all strength values determined from the actual slide. The writer regrets that there are no additional data on the excess hydrostatic pressure that would be helpful in a stability analysis over that given in the paper.

Mr. Gilboy has given a clear résumé of the action of the slide, and it is noted that he is in general agreement with the writer in all main features. He disagreed, however, on the action of the shell and transition after the initial failure had occurred. The action of this material after the initial failure is of minor importance in analyzing the cause of the Fort Peck slide; however, it is of major importance in the design of future hydraulic-fill dams in earthquake regions. Mr. Gilboy concludes definitely that there was liquefaction of the transition zone material and possibly the shell material during the slide.

The density of fill does coincide closely with the "minimum critical density" as pointed out by Mr. Gilboy. The margin of safety, however, is much greater than this comparison would indicate, since the critical density varied with every change in the material in the hydraulic fill. It is not an exaggeration to state that the critical density actually varied from the minimum to the maximum within a few inches of fill. Liquefaction over a sufficiently large area to cause trouble would have to include the strong with the weak. It is obvious, therefore, that the average critical density should be compared with the average fill density.

There are several other pertinent factors to this question, which were not mentioned by Mr. Gilboy, that should be emphasized. Undisturbed (frozen) 36-in. cores taken from the shell and from transition material after the slide showed no evidence of liquefaction, which is the major one of these factors. The fact that the "quick" condition on the surface, noted by Mr. Gilboy, was in the area where the transition zone and shell material sloughed into the settling core pool, as the shell moved out in a body, is another important factor. The core pool water trapped in the fissures and crack of the material was forced up through the mass, and a "quick" condition resulted at the surface. The remaining shell material, even that resting on the transition zone, moved out as a solid mass with very little disturbance on the surface except for tension cracks. In view of the overwhelming evidence that shows that the dredged sand did not liquefy and the obvious lack of any positive evidence that it did, it must be concluded that there was no liquefaction of the dredged sand.

---

[25] "Investigation of the Pendleton Levee Failure," report by the U. S. Waterways Experiment Station, Vicksburg, Miss., 1941.

The writer agrees fully with Mr. Gilboy that the water in the core pool settling into the crack left by the outward movement of the shell probably gave a little extra push that would not have been present in the rolled fill. However, the writer is confident that there would have been no basic difference in the nature of the slide except that the maximum distance that it moved might have been somewhat less (probably 900 ft instead of 1,000 ft).

Landslide activity stressed so strongly by Mr. Fahlquist had no bearing on the true cause of the slide. However, since this condition has been brought into the discussion, with the inference that it was not investigated, some comments are essential. Old landslides and faulting were quite extensive in the Bearpaw shale, and it was evident that a thorough investigation was absolutely necessary. Therefore, one of the first steps in the investigation of the foundation condition was to outline in detail all the faults and landslides. These conditions in the slide area were mapped very much in detail prior to the slide by explorations, including a tunnel into the abutment, shafts, and trenches, as well as core boring, and by actual excavation of the shafts, tunnels, and portal. It was concluded from the voluminous data available prior to the slide that the faulting and old landslide activity in this area would not cause any trouble, and the detail investigation after the slide substantiated this earlier conclusion. Even though there was considerable faulting in this area, as shown in the full report[12] on the slide, the Report of the Board of Consulting Engineers did not mention it as a possible cause of the slide. They did consider the possibility of grouting the so-called "A" fault on the left abutment, but after a thorough study had been made no grouting was considered necessary.

The 30-ft thick zone of blocky weathered shale found on the abutment, and referred to by Mr. Fahlquist, played only a secondary part in the slide. Movement definitely started around Station 15+00, due to the weak zone in the foundation, and as the mass moved out it carried a large part of this weathered shale with it. The writer is confident that the weathered shale in the abutment had no influence on the initial movement of the slide.

Mr. Fahlquist leaves the impression that the slide was due to some mystic geological condition involving old landslide activity that cores and undisturbed samples of the shale would not disclose, but that geological study of the region would. If there is any one point that stands out clearly from the writer's experience at Fort Peck, it is that a general geological study of the region is worthless for the investigation of any definite area for probable slides, unless it is accompanied by undisturbed samples of the rock in questionable areas. In any such investigation, the strength of the rock is essential, and it cannot be determined by a geological study of the region or even the immediate vicinity.

If, in all cases, the entire questionable mass was removed, as recommended by Mr. Fahlquist, there would, of course, be no need for undisturbed samples of the rock. However, at Fort Peck this procedure definitely was not economically feasible, and it bordered on the impossible.

In his closing statement, Mr. Fahlquist makes the following recommendations:

> "When such conditions are recognized, the only adequate exploration to confirm or disprove preliminary geologic conceptions is twofold: (1) A few well-selected and carefully executed borings to outline the extent of such geologic conditions, and (2) real life-size excavations to explore the condition fully, in area and in depth."

These recommendations are inadequate since they do not provide a means of determining whether the rock is strong enough to be stable. The Fort Peck slide is ample testimony to this fact, since the only thing missing from the original geological investigation was sufficiently large, undisturbed samples to determine the true character and strength of the upper 10 ft of the rock. This is the outstanding lesson to be learned by geologists and engineers from the Fort Peck slide.

Mr. Crosby minimizes the importance of the excess hydrostatic pressure in causing the slide, because other natural slides in this area occurred without this condition existing. The writer had no intention of leaving the impression that all slides were caused by the presence of excess hydrostatic pressure. Old slides along the river were definitely caused by undercutting which is an entirely different situation from that which existed in the Fort Peck slide. The slide at Snake Butte, Mont., was an old one that started moving again when the upper part was heavily loaded with quarry waste. These slides present no evidence from which one could logically conclude that excess hydrostatic pressure in the Fort Peck slide was not important.

It is agreed that the water that was present to develop the excess hydrostatic pressure did not come from the pores of the firm or sub-firm shale and bentonite seams. It came from the fractured and weathered zones in the shale and bentonite.

The writer agrees with Mr. Crosby in his conclusion "that 'liquefaction' of the bentonite previous to the slide did not exist." However, after a slight movement had occurred, the bentonite and shale were undoubtedly mixed with water and their strength considerably reduced. This, the writer believes, was the prime reason for the distance that the slide moved.

Mr. Crosby erroneously states that:

> "Numerous undisturbed samples of this shale and bentonite were taken, however, and numerous tests were made on them prior to the slide; but the true condition of the shale was not understood and the slide was not foreseen."

There were no undisturbed samples taken of the rock in the slide area, since the small core boring showed only sub-firm shale in this area. Sub-firm shale was found in numerous excavations to be a structurally strong rock. The geological explanation for the lack of weathered shale over the sub-firm shale in this area was that the river had scoured it off leaving only sub-firm shale. This conclusion at the time (without the benefit of hindsight) appeared entirely reasonable. Having been directly connected with the project for four years prior to the slide, the writer is firmly convinced that the actual strength and condition of the rock in the slide area could have been determined only by large undisturbed samples. It is rather far fetched to assume, regardless of how carefully the geology of the region was studied, that the true character and strength of the rock at any given location could be determined by this procedure.

The writer fully agrees that "Had the true conditions been understood, the dam could have been designed to meet those conditions safely." This is merely another way, however, of saying that hindsight is better than foresight

It has not been the intent of the writer in this discussion to minimize the importance of thorough geological investigations. However, it is certainly false security to rely too much on a geological study of the region as proposed by Mr. Fahlquist and Mr. Crosby. In the future, under such circumstances, the writer will take large undisturbed samples of all weak rocks regardless of what the geologist might find in a study of the region.

ON THE METHOD OF COMPLEMENTARY ENERGY

AND ITS APPLICATION TO STRUCTURES STRESSED BEYOND THE PROPORTIONAL LIMIT, TO BUCKLING AND VIBRATIONS, AND TO SUSPENSION BRIDGES

BY H. M. WESTERGAARD,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. I. K. SILVERMAN, GEORGE R. RICH, R. V. SOUTHWELL, AND H. M. WESTERGAARD.

SYNOPSIS

The method of complementary energy is a general method of structural mechanics. The basic law was stated by F. Engesser in a paper in 1889. He extended Castigliano's law of least work to apply beyond the range of Hooke's law by replacing work by complementary work, which is an integral of distance times increment of force. Engesser's paper is little known.

The purpose of the present paper is to give proof and demonstration of the method. The proof goes back to fundamentals and includes a re-examination of the fundamentals; this is needed to remove doubts about the ranges of applicability. The demonstration consists of representative applications and may be interpreted as an exploration of the field.

HISTORICAL NOTES

The method of complementary energy is an extension of Castigliano's method of least work. Alberto Castigliano[2] published his method during the Seventies in papers and a treatise. His principle of least work applies to statically indeterminate structures stressed within the range of Hooke's law and subject to the restriction that all significant deformations must be linear homogeneous functions of the loads. Castigliano showed that among all the

S. Andrews under the title "Elastic Stresses in Structures," Scott, Greenwood & Son, London, 1919.

statically possible states of stress in such a structure the correct one is that which makes the energy of the internal stresses a minimum. This state of stress satisfies automatically not only the requirement of equilibrium but also the requirement of geometrical continuity. L. F. Ménabréa[3] had stated this principle clearly for trusses in 1858, but his proof contained misunderstandings, and the method is credited justly to Castigliano.

Castigliano[4] himself gave the method its first extension; he stated a revised expression that must be made a minimum if imperfect fits of redundant members create initial stresses; and he applied this procedure to temperature stresses in a general discussion and in six examples.[5] H. Müller-Breslau[6] improved the procedure for temperature stresses and contributed much toward making Castigliano's method known. A useful and dependable critical account of the original works in the field was given by M. Grüning[7] in 1912. In the twentieth century Castigliano's method has become stock in trade; it holds a position today as one of several useful general procedures of structural mechanics. It is worthy of note that in a book published in 1936 R. V. Southwell[8] of Oxford University, Oxford, England, gave an attractive original derivation of Castigliano's principle, based on a discussion of self-strains.

The contribution that has the greatest interest for the present study was published by Fr. Engesser[9] in a paper in 1889. He derived the basic law of the method of complementary energy. It is a modification of Castigliano's law of least work in which work is replaced by complementary work or complementary energy. As work is an integral of force times increment of distance or of stress times increment of deformation, so is complementary work an integral of distance times increment of force or of deformation times increment of stress. Engesser's theory applies beyond the range of Hooke's law; it includes not only Castigliano's method but also Müller-Breslau's procedure for temperature stresses as special applications. In his review of the field in 1912 Grüning[10] quoted and discussed Engesser's contribution, but otherwise it has received little attention. A plausible explanation is that structural analysis has been concerned mainly with stresses below the proportional limit, and the applicability to buckling and vibrations had not been realized.

The method of complementary work or complementary energy is analogous to another method which has become important in structural statics; namely, the method based on the "principle of minimum of the potential energy by variation of the shape." It is advantageous to consider the two methods in conjunction. The basic principle of the second method is sometimes stated as a direct consequence of a general law of dynamics, but it can be derived from the simplest laws of statics. Daniel Bernouilli and Leonhard Euler[11] stated and used this principle in a special form in the first half of the eighteenth century. The method played a part in the nineteenth century. A mathematical paper published by W. Ritz[12] in 1908 gave new impetus to its use, which has been widespread since then. A number of applications are found in the writings of S. Timoshenko.[13]

THE LAWS OF LEAST ENERGY AND OF LEAST COMPLEMENTARY ENERGY

Since it is desirable that no doubts shall remain about the ranges of applicability, all the steps of the derivations of the basic theorems will be shown.

The Structure.—Fig. 1 represents a structure of general type. The black parts are joints, which, by a definition adopted here, are rigid bodies. The shaded parts are deformable members, which are attached to the joints. External forces and reactions are assumed to act on joints only. Since the joints may be three-, two-, or one-dimensional or may be without extension, and any number of joints may be assumed to exist, it is difficult to conceive of a structure to which this picture could not be adapted.

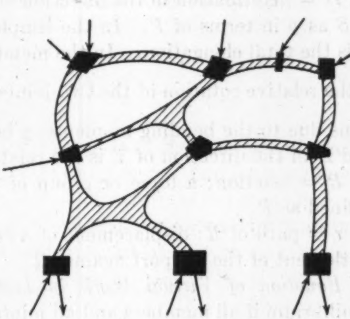

FIG. 1.—STRUCTURE OF GENERAL TYPE

Notation.—The notation applied to the structure in Fig. 1 requires explanations, which follow:

P = external load. The load P may be a single force P, or it may consist of a group of forces $c_1 P$, $c_2 P$, $c_3 P$, $\cdots$, all proportional to P and varying together when P varies. This conception makes it possible to consider a whole dead load or a whole live load as "a load"; which is in accordance with common usage of the word "load."

p = path of the load P during the deformation from a starting shape of the structure to an assumed shape. If P is a single constant force, p is the displacement of the point of application in the direction of P, and Pp is the work of P. If the load P is a group of forces, then p is defined by the statement that with the value of P remaining constant during the assumed deformation, the work of P is Pp. For example, if P is a total load uniformly distributed over the length of a beam, p is the increase of the average deflection.

S = stress in a member. The stress in the sense adopted here is interpreted as a load exerted by joints on a member, and is defined in the same way as P except for the restriction that all the forces constituting a particular stress S must be in equilibrium. If the member is a simple tension member in a truss, S may be taken as the total tension, and the load on the member is the two equal and opposite pulls, each equal to S, at the ends. There can be more than one stress in a member. For example, in a beam flat joints may be assumed at two adjacent cross sections a distance dx apart. The member between these two joints has two stresses: One is the bending moment M, which consists of two equal and opposite couples exerted by the joints; the other is the transverse shear V, which consists of two equal and opposite shearing forces and a supplementary balancing couple Vdx at one of the joints. Instead one may in this case assume two members occupying the same space between the cross sections, one resisting M and the other V.

D = deformation in the direction of S; D is the path of S, defined in terms of S as p in terms of P. In the simple tension member with total tension S, D is the total elongation. In the member in the beam D in the direction of M is the relative rotation of the two joints, that is, $-\frac{d^2y}{dx^2}\,dx$ if y denotes the deflections due to the bending moments, y being measured from the starting shape; and D in the direction of V is the relative sliding of the joints.

R = reaction; a force or group of forces exerted by a support, otherwise defined as P.

r = path of R; displacement of a support in the direction or R; $-r$ is the settlement of the support against R.

Equation of Virtual Work in Infinitesimal Form.—The structure is in equilibrium if all members and all joints are in equilibrium. The members are loaded only by the stresses S, and are automatically in equilibrium by the definition of the stresses. A joint, by definition, is a rigid body. The equilibrium of a rigid body can be investigated by assuming an arbitrary infinitesimal movement of it while the forces remain constant. If during any such movement the sum of work of all the forces is zero except for an infinitesimal quantity of second or higher order, the rigid body is in equilibrium. Assume an arbitrary infinitesimal movement of each joint, whereby the deformations p, D, and r increase by the amounts δp, δD, and δr. The forces acting on all the joints are the forces constituting the loads P, the stresses reversed or $-S$, and the reactions R. The condition that the sum of work of all the forces on all the joints must be zero is expressed by the equation

$$\sum P\,\delta p - \sum S\,\delta D + \sum R\,\delta r = 0 \quad \text{.................} (1)$$

This equation will be recognized as the equation of virtual work in infinitesimal form; it states a principle that has played a great part in mechanics. Eq. 1 is a general condition of equilibrium, unrestricted by any requirement of linearity of the relations between the deformations, stresses, and loads; that is, unrestricted by any law of superposition.

Initial Assumption.—Changes of temperature can be considered to have taken place in advance, before the forming of the starting state. Then it becomes feasible to assume, and it will be assumed, that in all operations that need be considered in the analysis each stress S is a definite continuous function of the deformations D of the member in which it belongs, and conversely each deformation is a definite continuous function of the stresses in the member.

Energy.—Now consider a series of changes of shape, a variation of the shape, during which the loads and the positions of the supports remain constant; that is, the values of P and r remain constant. Each joint is moved from the starting position into an arbitrarily assumed position; thereby the structure is changed from the starting shape to an assumed shape. The members remain attached to the joints, so that continuity is maintained, but the requirements of equilibrium are ignored in this operation; that is, the geometrical requirements are respected, while the statical requirements are abandoned temporarily. The stresses S will be the proper definite functions of the deformations D. Then, for each assumed shape the structure and the loads can be said to have a potential energy equal to

$$T = \sum \int_{D_0}^{D} S\,dD - \sum P\,p \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which the lower limits D_0 are chosen arbitrarily and the summations include all stresses and loads. The phrase "potential energy" can be used here because the stresses are definite functions of the deformations in the operations of the analysis. An infinitesimal variation of the assumed shape causes an increment, a first variation, of the potential energy equal to

$$\delta T = \sum S\,\delta D - \sum P\,\delta p \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Let the requirements of equilibrium be imposed again. Then Eq. 1 must be satisfied. Since $\delta r = 0$ in the variation considered, it follows that

$$\delta T = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

That is, if not only all the geometrical requirements but also all the statical requirements are to be satisfied, the first variation of the potential energy must be zero; that is, the potential energy must be a minimum or a maximum. Further arguments, omitted here, show that a stable equilibrium requires that T be a minimum. The statement

$$T = \min \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

is interpreted then with the reservation that T is normally a minimum, but under some circumstances the minimum may be replaced by a maximum. Eqs. 5 and 2 together state the "law of minimum of the potential energy by variation of the shape." Eq. 5 like Eq. 1 is unrestricted by any law of superposition.

Assumption of Superposition of Deformations, and the Equation of Virtual Work in Finite Form.—It will now be assumed that the law of superposition (or linearity) applies in a limited form; namely to deformations only, without involving loads, stresses, and reactions: it is assumed that if p', D', r' and p'', D'', r'' are two geometrically possible sets of deformations p, D, r, then $p'+p''$, $D'+D''$, $r'+r''$ are a possible set, provided that all the deformations involved are within some range. If this law is assumed, δp, δD, and δr in Eq. 1 may be replaced by p', D', and r'; so that

$$\sum P\,p' - \sum S\,D' + \sum R\,r' = 0 \qquad (6)$$

This is the equation of virtual work in finite form, which has been important in structural mechanics since the Seventies, when Otto Mohr applied it to trusses. It is noted that p', D', r' are not the deformations produced by the loads P.

Eq. 6 may be restated in the form

$$\sum P'\,p - \sum S'\,D + \sum R'\,r = 0 \qquad (7)$$

in which P', S', R' are a statically possible set of values of the loads, stresses, and reactions. A possible form of Eq. 7 is

$$\sum p\,\delta P - \sum D\,\delta S + \sum r\,\delta R = 0 \qquad (8)$$

in which δP, δS, δR are a statically possible set of increments of P, S, R.

Complementary Energy.—The preparations have now been made for the study of the second fundamental type of variation; namely, a variation of the state of stress, during which the statical requirements of equilibrium are the ones that remain satisfied, while the geometrical requirements of continuity are abandoned temporarily. As before, P and r are considered to remain constant, but now the deformations D are interpreted as functions of the stresses S, and values S_0 are arbitrarily chosen lower limits of the stresses. Then the complementary energy will be defined by the expression

$$U = \sum \int_{S_0}^{S} D\,dS - \sum r\,R \qquad (9)$$

An infinitesimal variation from any one of the statically possible states of stress to an adjacent statically possible state gives U an increment, a first variation, equal to

$$\delta U = \sum D\,\delta S - \sum r\,\delta R \qquad (10)$$

If the set of values of D and r happen to satisfy the geometrical requirements of continuity, then these values must satisfy Eq. 8 with $\delta P = 0$. It follows that

$$\delta U = 0 \qquad (11)$$

That is, the first variation of U vanishes; the complementary energy, U, is a minimum or a maximum, like the energy T ordinarily a minimum. The statement

$$U = \min \qquad (12)$$

is interpreted with the same reservation that was applied to Eq. 5: under abnormal circumstances the minimum may be changed into a maximum. Eq. 12, with U defined by Eq. 9, is the law of least complementary energy. This minimum is produced by a variation of the state of stress.

Analogy.—A comparison of Eqs. 1 to 5 with Eqs. 8 to 12, in order, shows that a complete analogy exists between the two laws of least energy and least complementary energy, with a one to one correspondence of the quantities, as follows: in the shifting from one principle to the other the quantities P, S, R, T, U, p, D, r are replaced by the same quantities in the reversed order.

Castigliano's Principle as Special Case.—When Hooke's law applies and a stress-less state can be and is chosen as starting state, and the lower limits S_0 are chosen as zero, the part of the complementary energy contributed by the stresses, the first sum in Eq. 9, becomes

$$U_i = \tfrac{1}{2} \sum D\,S \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

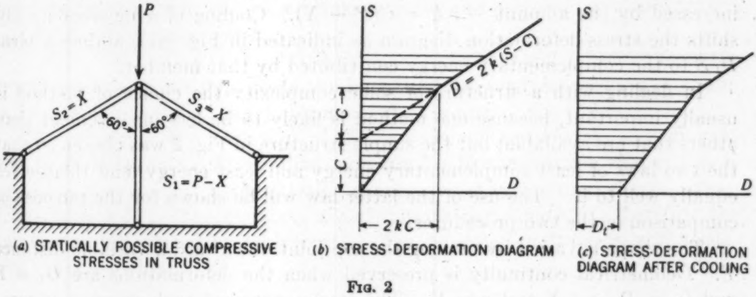
which is the same as the internal energy of stresses. If the supports have not moved, then $r = 0$. In this special yet general case the law of least complementary energy becomes

$$U_i = \min \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

which is Castigliano's principle of least work, or, the principle of minimum of the internal energy by variation of the state of stress.

APPLICATION TO A SIMPLE STATICALLY INDETERMINATE STRUCTURE STRESSED BEYOND THE PROPORTIONAL LIMIT

The simple truss in Fig. 2(*a*) will serve as an example. The stresses are total stresses, positive in compression. The state of stress is varied by varying X. The three members are assumed to be alike, with the stress-deformation diagram shown in Fig. 2(*b*). The supports are assumed not to have moved.



(*a*) STATICALLY POSSIBLE COMPRESSIVE STRESSES IN TRUSS (*b*) STRESS-DEFORMATION DIAGRAM (*c*) STRESS-DEFORMATION DIAGRAM AFTER COOLING

FIG. 2

When none of the stresses exceeds the proportional limit $2\,C$, the complementary energy is the same as the stress energy, which is

$$U = \tfrac{1}{2}\,k\,(P - X)^2 + k\,X^2 \ldots\ldots\ldots\ldots\ldots (15)$$

In Eq. 15, U must be a minimum by Castigliano's principle, which gives $X = \dfrac{P}{3}$.

When $P > 3\,C$, the stress in the vertical member will exceed the proportional limit $2\,C$. The complementary energy is determined by adding areas such as the shaded area in Fig. 2(*b*). If the proportional limit is not exceeded in the inclined members, the total complementary energy is

$$U = k\,C^2 + k\,(P - X - C)^2 + k\,X^2 \quad\ldots\ldots\ldots\ldots\ldots(16)$$

In Eq. 16, U becomes a minimum when

$$X = \frac{P - C}{2} = S_2 = S_3 \quad\ldots\ldots\ldots\ldots\ldots(17a)$$

and

$$S_1 = \frac{P + C}{2} \quad\ldots\ldots\ldots\ldots\ldots(17b)$$

Eqs. 17 apply when $3\,C < P < 5\,C$. If $P > 5\,C$, the complementary energy is

$$U = 3\,k\,C^2 + k\,(P - X - C)^2 + 2\,k\,(X - C)^2 \quad\ldots\ldots\ldots(18)$$

which becomes a minimum when

$$X = \frac{P + C}{3} = S_2 = S_3 \quad\ldots\ldots\ldots\ldots\ldots(19a)$$

and

$$S_1 = \frac{2\,P - C}{3} \quad\ldots\ldots\ldots\ldots\ldots(19b)$$

Computations such as these are simplified in less simple applications by expressing the derivatives that determine the minimum, without computing the value of the complementary energy itself.

If the support of the vertical member in Fig. 2(a) settles a distance c downward, the path of the corresponding upward reaction R is $r = -\,c$, and U is increased by the amount $-\,r\,R = c\,(P - X)$. Cooling of a member merely shifts the stress-deformation diagram as indicated in Fig. 2(c), adding a term $D_t\,S$ to the complementary energy contributed by that member.

In dealing with a structure of some complexity the choice of method is usually important, because one method is likely to be less inconvenient than others that are available; but the simple structure in Fig. 2 was chosen so that the two laws of least complementary energy and least energy lend themselves equally well to it. The use of the latter law will be shown for the purpose of comparison of the two procedures.

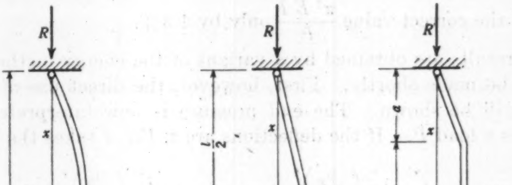
The shape is varied by moving the top joint downward a variable distance Y. Geometrical continuity is preserved when the deformations are $D_1 = Y$ and $D_2 = D_3 = \frac{1}{2}\,Y$ and $p = Y$. The strain energy of each member is measured by an area under the lines in Fig. 2(b). It is justifiable to call this quantity energy because the stress is a definite function of the deformation in the operations of the analysis; the quantity need not be energy in every physical sense; it is energy in the analysis. If the proportional limit has been exceeded in the vertical member only, the energy in Eq. 2 becomes

$$T = \left(\frac{Y^2}{4\,k} + C\,Y - k\,C^2\right) + \frac{1}{k}\left(\frac{Y}{2}\right)^2 - P\,Y \quad\ldots\ldots\ldots(20)$$

In Eq. 20, T is a minimum when $Y = k\,(P - C)$, which reproduces the stresses in Eqs. 17.

BUCKLING OF COLUMN WITH HINGED ENDS

When a column buckles under a critical load, the movement of the loaded end, the shortening of the chord, is proportional to the square of the lateral deflections; this is a departure from linearity and from the law of superposition; but the law of superposition of deformations will hold with good approximation in the significant applications if the starting shape is chosen close to the final shape.



(a) (b) (c)

FIG. 3.—STARTING SHAPES OF COLUMN

Fig. 3(*a*) shows a plausible starting shape for a hinged-ended column, held between two fixed blocks. The blocks give the end pressure the character not of a load but of a reaction R.

Let: z = deflection in the starting shape; y = additional deflection from the starting shape to the final shape, making the total final deflection $y + z$; and EI = modulus of elasticity times moment of inertia of the cross section.

In computing the variation of the complementary energy according to Eq. 10, S is taken as the bending moment Rz in the starting shape; this is approximately correct if the starting shape is close to the final shape. Then δS becomes $z\,\delta R$. The members are of infinitesimal length dx; therefore the summation is replaced by an integral. The deformation D becomes the relative change of slope

$$-\frac{d^2y}{dx^2}\,dx = \left(\frac{R\,z}{E\,I} + \frac{d^2z}{dx^2}\right)dx \qquad (21)$$

The displacement r is zero since the end blocks do not move. Thus one finds

$$\delta U = \int_0^l \left(\frac{R\,z}{E\,I} + \frac{d^2z}{dx^2}\right)dx\;(z\,\delta R) = 0 \qquad (22)$$

which gives the approximate formula

$$R = -\frac{\displaystyle\int_0^l z\,\frac{d^2z}{dx^2}\,dx}{\displaystyle\int_0^l \frac{z^2\,dx}{E\,I}} \qquad (23)$$

By choosing as a starting shape the parabola

$$z = 4\,c\,l^{-2}\,(l\,x - x^2) \qquad (24)$$

and assuming $E\,I$ constant, one finds by easy integrations

$$R = \frac{10\,E\,I}{l^2} \qquad (25)$$

which exceeds the correct value $\frac{\pi^2\,E\,I}{l^2}$ only by 1.3%.

The same results are obtained by a variant of the energy method to which reference will be made shortly. First, however, the direct use of the law of least energy will be shown. The end pressure is now interpreted not as a reaction but as a load P. If the deflections are z, Eq. 2 takes the form

$$T = \tfrac{1}{2}\int_0^l E\,I\left(\frac{d^2z}{dx^2}\right)^2 dx - P\cdot\tfrac{1}{2}\int_0^l\left(\frac{dz}{dx}\right)^2 dx \qquad (26)$$

The variation δT vanishes only when P has the critical value that makes $T = 0$. This gives

$$P = \frac{\displaystyle\int_0^l E\,I\left(\frac{d^2z}{dx^2}\right)^2 dx}{\displaystyle\int_0^l\left(\frac{dz}{dx}\right)^2 dx} \qquad (27)$$

With z as in Eq. 24 and $E\,I$ constant, Eq. 27 gives $P = 12\,E\,I\,l^{-2}$ which is 22% too great. The method of complementary energy gives the same result when z is taken as in Fig. 3(b); the numerator in Eq. 23 then being computed as c times the change of slope at the middle of the column. With the starting shape in Fig. 3(c) the method of complementary energy gives $R = \frac{6\,E\,I}{2\,a^2 + 3\,a\,b}$, which has its smallest and therefore most plausible value, $10.67\,E\,I\,l^{-2}$, when $a = \frac{3\,l}{8}$.

The comparison just made indicates superiority of the method of complementary energy over the direct application of the method of the potential energy to columns; but, as has been indicated, a variant of the energy method, applicable to columns, is available. S. Timoshenko[14] has described and used it. This improved variant can be explained by noting that the numerator in Eq. 27 is improved by replacing $\frac{d^2z}{dx^2}$ by $-\frac{P\,z}{E\,I}$. Then the formula becomes

$$P = \frac{\displaystyle\int_0^l\left(\frac{dz}{dx}\right)^2 dx}{\displaystyle\int_0^l\frac{z^2\,dx}{E\,I}} \qquad (28)$$

Eq. 28 can be rewritten in the form of Eq. 23. That is, Timoshenko's variant of the energy method for columns gives the same results as the method of complementary energy.

---

[14] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., 1936, p. 81.

COLUMN WITH INITIAL CURVATURE

If the column that has been under discussion is slightly curved before loading, with the initial deflections z_0, and if z still denotes the total deflections in the starting shape, Eq. 22 will be changed to

$$\delta U = \int_0^l \left(\frac{R\,z}{E\,I} + \frac{d^2z}{dx^2} - \frac{d^2z_0}{dx^2} \right) dx\,(z\,\delta R) = 0 \dots\dots\dots\dots (29)$$

Assume that the shape before loading makes it plausible to choose z proportional to z_0. Denote by Q the critical value of R defined by Eq. 23 for $z_0 = 0$. Then Eq. 29 gives

$$R - \left(1 - \frac{z_0}{z}\right) Q = 0 \dots\dots\dots\dots (30)$$

or,

$$\frac{z}{z_0} = \frac{Q}{Q - R} \dots\dots\dots\dots (31)$$

Eq. 31 defines a magnification factor for the deflections. Such factors will be discussed again later.

GREATEST LOAD ON AN INITIALLY CURVED COLUMN STRESSED BEYOND THE PROPORTIONAL LIMIT

If the column in Fig. 3(*a*) is stressed beyond the proportional limit, it may be plausible to assume a law of deformations of the type,

$$\text{Change of curvature} = \frac{1}{E_r\,I}\,(M + F^{-2}\,M^3) \dots\dots\dots\dots (32)$$

in which E_r and F are functions of the end pressure R and dependent on the material and the shape of the cross section; E_r being a reduced modulus of elasticity, and F a coefficient measurable in inch-pounds. The theory developed by Engesser (from 1889), A. Considère (1891), F. S. Yasinsky (1895), and Theodor von Kármán, M. Am. Soc. C. E., (1910),[15] furnishes a method of computing E_r; for example, this method gives for a rectangular cross section

$$E_r = \frac{4\,E\,E_t}{(\sqrt{E} + \sqrt{E_t})^2} \dots\dots\dots\dots (33)$$

in which E_t is the tangent modulus of elasticity. The theory also will make it possible[16] to establish reasonable values of F. Moreover, it should be possible to determine both E_r and F by tests of short specimens under eccentric pressure.

Let z_0 denote, as before, the initial deflections before loading, and z the total starting deflections under the pressure R. With Eq. 32 accepted, Eq. 29

---

[15] For explanation of the basis of the theory and for references, see "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., 1936, pp. 157–159.

[16] See, for example, the paper "Strength of Steel Columns," by H. M. Westergaard and William R. Osgood, Members, Am. Soc. C. E., *Transactions*, A. S. M. E., Vol. 50, 1928, No. 17, p. 65.

changes into the following expression of the law of least complementary energy:

$$\frac{dU}{dR} = \int_0^l \left[\frac{1}{E_r\, I} (R\, z + F^{-2}\, R^3\, z^3) + \frac{d^2 z}{dx^2} - \frac{d^2 z_0}{dx^2} \right] z\, dx = 0 \quad \text{.....(34)}$$

Let z_0 be assumed and z chosen as follows:

$$z_0 = c_0 \sin \frac{\pi\, x}{l} \quad \text{.....(35a)}$$

and

$$z = c \sin \frac{\pi\, x}{l} \quad \text{.....(35b)}$$

and denote,

$$Q = \frac{\pi^2\, E_r\, I}{l^2} \quad \text{.....(36)}$$

Then Eq. 34 gives

$$R\, c + \frac{3}{4} \frac{(R\, c)^3}{F^2} = Q\, (c - c_0) \quad \text{.....(37)}$$

In the course of a test in a laboratory, as the distance between the end blocks is reduced, the maximum deflection c will increase gradually and may serve as a measure of the progress of the test. The end pressure R will be a function of c, dependent on the initial deflection c_0. It is desired to determine the maximum value of R as a function of c, for different definite values of c_0 and l.

It is noted that E_r in Eq. 36 is a function of R; therefore Q in Eqs. 36 and 37 is a function of R. With this in view Eq. 37 shows that in the special case of $c_0 = 0$, the maximum value of R occurs when $c = 0$, and is equal to Q, as it should be in accordance with the theory initiated by Engesser. With $Q = R$ and R chosen, Eq. 36 can be solved for l, thus serving as a formula for the idealized case of an initially straight column.

When the column is curved before loading (that is, when $c_0 > 0$), Q loses its significance as a maximum load and becomes merely a quantity introduced for convenience and defined by an equation. To make R a maximum the condition $\frac{dR}{dc} = 0$ is imposed. Since Q is a function of R, it follows that $\frac{dQ}{dc} = 0$. Under these conditions, by applying the operators $3 - c \frac{d}{dc}$ and $c \frac{d}{dc} - 1$ to Eq. 37, one finds

$$2\, R\, c = Q\, (2\, c - 3\, c_0) \quad \text{.....(38a)}$$

and

$$\frac{3\, (R\, c)^3}{2\, F^2} = Q\, c_0 \quad \text{.....(38b)}$$

respectively. Elimination of c from Eqs. 38 gives

$$c_0 = \frac{4\, F}{9\, Q} \left(\frac{Q}{R} - 1 \right)^{3/2} \quad \text{.....(39)}$$

or, with Q substituted from Eq. 36,

$$c_0 = \frac{4\,F\,l^2}{9\,\pi^2\,E_r\,I}\left(\frac{\pi^2\,E_r\,I}{R\,l^2} - 1\right)^{3/2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Eq. 40 is not a design formula, but may lend itself to interpretations of tests. If E_r and F are numerically known functions of R, the values of R and l may be chosen, and the greatest initial deflection c_0 permitting these values may be computed by Eq. 40.

If Eq. 32 is replaced by the simpler but probably less plausible formula,

$$\text{Change of curvature} = \frac{1}{E_r\,I}\,(M + F^{-1}\,M^2) \ldots\ldots\ldots\ldots (41)$$

the same procedure of analysis gives, instead of Eq. 40,

$$c_0 = \frac{3\,F\,l^2}{32\,\pi\,E_r\,I}\left(\frac{\pi^2\,E_r\,I}{R\,l^2} - 1\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Buckling of a Thin Circular Elastic Plate with Simply Supported Edge Under a Uniform Pressure at the Edge

A solution of this problem was indicated by G. H. Bryan[17] in 1891. The differential equation for the slope in the radial direction is solved by a Bessel function of order one. When Poisson's ratio is 0.3, this exact solution gives the following value of the critical pressure per unit of length:

$$R = \frac{4.62\,E\,I}{a^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

in which: I = moment of inertia of the cross section per unit of width; and a = radius of the plate.

The application of the method of complementary energy to this problem is not more convenient than the use of Bessel functions, but it will serve the purpose of an illustration. The procedure can be used in more complicated related problems, involving, for example, a varying thickness.

The following additional notation is used:

r = radial distance from the center of the plate.

m_r = bending moment in the radial direction per unit of width of the circumferential section on which it acts.

m_θ = bending moment in the circumferential direction per unit of width of the radial section on which it acts; both m_r and m_θ are measurable in inch-pounds per inch, or, in pounds.

z = starting deflection.

ζ = supplementary deflection, making the final deflection $z + \zeta$.

c = z at center.

$f = f(r)$ = stress function, measurable in inch-pounds.

X = constant to be determined.

μ = Poisson's ratio.

---

[17] *Proceedings*, London Mathematical Soc., Vol. 22, 1891, p. 54; also, "Theory of Elastic Stability," by S. Timoshenko, 1936, pp. 367–369.

It is permissible to assume that z, ζ, and f are functions of r only. When z is chosen so that the values of ζ will be insignificant relative to the values of z, the bending moments can be expressed by the formulas,

$$m_r = R\,z + \frac{f}{r} \quad \text{(44a)}$$

and

$$m_\theta = R\,z + \frac{df}{dr} \quad \text{(44b)}$$

A simple examination shows that no matter what differentiable function f is chosen, the moments in Eqs. 44 maintain equilibrium. The variation of the state of stress therefore is reduced to the variation of R and f. When the edge is simply supported, $z = 0$ and $f = 0$ at the edge.

As in the study of columns, R is interpreted as a reaction exerted by a strong support in a fixed position. The changes of curvature in the directions of m_r and m_θ, measured from the starting shape to the final shape, are $-\dfrac{d^2\zeta}{dr^2}$ and $-\dfrac{1}{r}\dfrac{d\zeta}{dr}$, respectively. Accordingly the law of least complementary energy takes the form

$$\delta U = \int_0^a 2\,\pi\,r\,dr \left[-\frac{d^2\zeta}{dr^2}\,\delta m_r - \frac{1}{r}\frac{d\zeta}{dr}\,\delta m_\theta \right] = 0 \quad \text{(45)}$$

To obtain an approximate solution the following expressions are chosen:

$$z = c\left(1 - \frac{r^2}{a^2}\right) \quad \text{(46a)}$$

and

$$f = c\,(X - R)\left(r - \frac{r^3}{a^2}\right) \quad \text{(46b)}$$

By Eqs. 44 the corresponding moments are

$$m_r = c\,X\left(1 - \frac{r^2}{a^2}\right) \quad \text{(47a)}$$

and

$$m_\theta = c\,X\left(1 - \frac{3\,r^2}{a^2}\right) + \frac{2\,c\,R\,r^2}{a^2} \quad \text{(47b)}$$

The bending moments define the corresponding changes of curvature:

$$-\frac{d^2\zeta}{dr^2} = \frac{1}{E\,I}\,(m_r - \mu\,m_\theta) + \frac{d^2z}{dr^2}$$

$$= \frac{c}{E\,I}\left\{ X\left[1 - \mu - (1 - 3\,\mu)\,\frac{r^2}{a^2}\right] - \frac{2\,\mu\,R\,r^2}{a^2} \right\} - \frac{2\,c}{a^2} \quad \text{(48)}$$

and

$$-\frac{1}{r}\frac{d\zeta}{dr} = \frac{1}{E\,I}\,(m_\theta - \mu\,m_r) + \frac{1}{r}\frac{dz}{dr}$$

$$= \frac{c}{E\,I}\left\{ X\left[1 - \mu - (3 - \mu)\,\frac{r^2}{a^2}\right] + \frac{2\,R\,r^2}{a^2} \right\} - \frac{2\,c}{a^2} \quad \text{(49)}$$

By substituting from Eqs. 47, 48, and 49 in Eq. 45, and carrying out the integrations one finds

$$\frac{3\,E\,I}{\pi\,a^2\,c^2}\,\delta U = \left[\,4\,X - (3+\mu)\,R\,\right]\delta X$$

$$+\left[\,-\,(3+\mu)\,X + 4\,R - \frac{6\,E\,I}{a^2}\,\right]\delta R = 0 \quad \text{(50)}$$

Eq. 50 gives

$$X = \frac{3+\mu}{4}\,R \quad \text{(51}a\text{)}$$

and

$$R = \frac{24\,E\,I}{(7+\mu)\,(1-\mu)\,a^2} \quad \text{(51}b\text{)}$$

With $\mu = 0.3$, Eqs. 51 give $R = 4.70\,\frac{E\,I}{a^2}$ which is only 1.7% greater than the correct value in Eq. 43.

By the choice,

$$z = c\cos\frac{\pi\,r}{2\,a} \quad \text{(52}a\text{)}$$

and

$$f = c\,(X - R)\,r\cos\frac{\pi\,r}{2\,a} \quad \text{(52}b\text{)}$$

instead of Eqs. 46, the slightly better value $R = 4.66\,\frac{E\,I}{a^2}$ was obtained with $\mu = 0.3$.

APPLICATION TO VIBRATION OF BEAMS

If an elastic beam vibrates freely in one of its modes, the deflections at the time t may be stated as

$$\eta = (z + y)\cos\omega\,t \quad \text{(53)}$$

in which ω is a constant defining the period as $\frac{2\,\pi}{\omega}$, and z and y are functions of the distance x measured along the beam. The function z will be chosen so that the values of y are relatively small. Then z may be interpreted as a starting deflection and y as a supplementary deflection, both referring to the times when $\cos\omega\,t = 1$.

Let X denote the bending moment at any point due to an imagined static load defined as the product of z times the weight w per unit of length; w may be constant or a function of the distance x; X will be a function of x and will be measurable in lb-in.^{2} When $\cos\omega\,t = 1$, the inertia force per unit of length is $\frac{\omega^2}{g}\,w\,(z + y)$, in which g is the acceleration due to gravity; $\frac{w}{g}$ is the mass per unit of length. When the contributions from y can be ignored, the bending moment due to the inertia forces becomes

$$M = \frac{\omega^2}{g}\,X \quad \text{(54)}$$

The use of the inertia forces converts the problem into one of statics. The quantity $\frac{\omega^2}{g}$ now may be interpreted as an adjustable reaction, playing the same rôle as R in the application to columns. Then

$$\delta M = X\,\delta\left(\frac{\omega^2}{g}\right) \qquad (55)$$

and the variation of the complementary energy becomes

$$\delta U = \int\left(\frac{M}{E\,I} + \frac{d^2z}{dx^2}\right) dx\,\delta M = \delta\left(\frac{\omega^2}{g}\right)\int\left(\frac{\omega^2 X}{E\,I\,g} + \frac{d^2z}{dx^2}\right) X\,dx = 0 \qquad (56)$$

Eq. 56 gives

$$\omega^2 = -\frac{\int X\,\frac{d^2z}{dx^2}\,dx}{\int \frac{X^2\,dx}{E\,I\,g}} \qquad (57)$$

from which the period may be computed as $\frac{2\,\pi}{\omega}$.

It is of interest to compare Eq. 57 with the next equation, which represents Rayleigh's[18] method. The left side of the equation is twice the kinetic energy when $\cos\omega\,t = 0$; the right side is twice the internal potential energy when $\cos\omega\,t = 1$; and either side is twice the total mechanical energy:

$$\omega^2\int\frac{w}{g}\,z^2\,dx = \int E\,I\left(\frac{d^2z}{dx^2}\right)^2 dx \qquad (58)$$

When the deflection z is stated approximately, Eq. 58 gives an approximate value of ω^2. The example that follows will show that Eq. 58 requires a more accurate statement of z than does Eq. 57 for the same degree of approximation in the value of ω.

A cantilever of length l, with a fixed support at $x = 0$, and with w and $E\,I$ constant, is chosen as example. An exact solution[19] of the proper differential equation gives an expression for the extreme deflections $z + y$ in terms of two hyperbolic and two trigonometric functions. Thereby the value of ω in the first mode of vibration is found to be

$$\omega = 3.516\,\omega_0 \qquad (59)$$

in which ω_0 denotes the quantity

$$\omega_0 = \sqrt{\frac{E\,I\,g}{w\,l^4}} \qquad (60)$$

In an approximate solution by the method of complementary energy the starting curve may be taken as a parabola,

$$z = \frac{c\,x^2}{l^2} \qquad (61)$$

---

[18] "Theory of Sound," by Lord Rayleigh, 1877, 2d Ed., MacMillan & Co., Vol. 1, 1894, pp. 109 and 257; see also "Vibration Problems in Engineering," by S. Timoshenko, Van Nostrand Co., 1928, pp. 55–60.

[19] See "Vibration Problems in Engineering," by S. Timoshenko, Van Nostrand Co., 1928, p. 234.

Then

$$X = -\frac{w\,l^2\,c}{12}\left[\left(\frac{x}{l}\right)^4 - \frac{4\,x}{l} + 3\right] \dots\dots\dots\dots (62)$$

When these functions are substituted in Eq. 57, one finds

$$\omega = \omega_0\sqrt{\frac{162}{13}} = 3.530\,\omega_0 \dots\dots\dots\dots (63)$$

which differs only by 0.4% from the correct value in Eq. 59.

Exactly the same result can be obtained by Rayleigh's method, with Eq. 58, but the function z must be chosen much closer to the true deflections; the function z equal to the deflection under a uniform load will serve the purpose.[20] If z were taken from Eq. 61, Eq. 58 would give $\omega = \omega_0\,\sqrt{20} = 4.47\,\omega_0$, which is 27% too great.

If a straight line, $z = \frac{c\,x}{l}$, is chosen as starting shape instead of the parabola in Eq. 61, the method of complementary energy gives $\omega = \omega_0\sqrt{\frac{140}{11}} = 3.57\,\omega_0$. Rayleigh's method gives the same result when z is chosen as the deflection due to a concentrated load at the free end.[21]

Stabilizing Loads

When a load producing buckling is reversed, it becomes a stabilizing load; but it can still be studied by the theory of buckling. The general theorems which are needed in subsequent applications of the method of complementary energy are derived most conveniently by considering the energy as a function of the shape. The derivations will be shown in brief form.[22]

It is assumed that any shape of the structure that is geometrically possible, when continuity is maintained, can be defined by assigning a definite set of values to a set of parameters $u_0, u_1, u_2, \cdots u_n, \cdots$. It is assumed that these parameters define any internal deformation by a linear equation of the form

$$D = D_0\,u_0 + D_1\,u_1 + D_2\,u_2 + \cdots + D_n\,U_n + \cdots = \sum_{0,1,2,\dots}^{n} D_n\,u_n \dots (64)$$

Besides, it is assumed that each member obeys Hooke's law. Then each stress will be a linear function of the parameters, and the strain energy will be a quadratic function of the parameters.

Two loads, P and Q, are considered. It is assumed that the path p of P can be stated adequately as a linear function of the parameters,

$$p = \sum_{1,2,\dots}^{n} p_n\,u_n \dots\dots\dots\dots (65)$$

but that a quadratic function of the parameters is required for an adequate statement of the path q of Q. It will be assumed that a special choice of parameters has made it possible to state the path q as

---

[20] "Vibration Problems in Engineering," by S. Timoshenko, Van Nostrand Co., 1928, p. 59.

[21] *Loc. cit.*, p. 58.

[22] A fuller account of the theory represented by Eqs. 64 to 73 and 78 to 80 and explanations of the special terminology are given in the paper, "Buckling of Elastic Structures," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. 85 (1922), p. 576, especially pp. 604–637.

$$q = -q_0 u_0 - \tfrac{1}{2} \sum_{1,2,\ldots}^{n} q_n u_n^2 \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

and the strain energy as

$$V = \tfrac{1}{2} V_0 u_0^2 + \tfrac{1}{2} \sum_{1,2,\ldots}^{n} Q_n q_n u_n^2 \ldots\ldots\ldots\ldots\ldots (67)$$

with all the coefficients q_0, q_n, V_0, and Q_n positive and all of the values Q_n different from one another. That this combination of relations is not only possible, but typical of buckling and stabilizing loads, will be brought out by the discussion that follows.

With Eqs. 65 to 67 accepted, the principle of minimum of the potential energy by variation of the shape takes the form,

$$T = V - Q\,q - P\,p = \tfrac{1}{2} V_0 u_0^2 + \tfrac{1}{2} \sum_{1,2,\ldots}^{n} Q_n q_n u_n^2$$

$$+ Q \left(q_0 u_0 + \tfrac{1}{2} \sum_{1,2,\ldots}^{n} q_n u_n^2 \right) - P \sum_{1,2,\ldots}^{n} p_n u_n \ldots\ldots\ldots (68)$$

$$\delta T = 0, \quad \text{or,} \quad \frac{\partial T}{\partial u_n} = 0 \qquad \text{for } n = 0, 1, 2, \cdots \ldots\ldots\ldots (69)$$

Eqs. 68 and 69 will be applied to investigate a series of four actions, in which u_n will be denoted successively u_n, $\bar{u}_n$, $\bar{\bar{u}}_n$, and u_n. Table 1 will serve as a summary of the results.

TABLE 1.—SUMMARY OF THEORY OF BUCKLING AND STABILIZING LOADS

Action	Definition	Value of parameter u_n for $n = 1, 2, 3, \cdots$	Equation No.
Astatic	$P = 0, Q = -Q_n$	u_n = any value, others $= 0$	71
Orthostatic	$P \neq 0, Q = 0$	$\bar{u}_n = \dfrac{P\,p_n}{Q_n\,q_n} = \dfrac{Q}{Q_n}\,\bar{\bar{u}}_n$	73, 77
Relaxed	$P \neq 0, Q > 0$, V reduced	$\bar{\bar{u}}_n = \dfrac{P\,p_n}{Q\,q_n} = \dfrac{Q_n}{Q}\,\bar{u}_n$	77, 73
Heterostatic	$P \neq 0, Q \neq 0$, V restored	$u_n = \dfrac{Q_n}{Q_n + Q}\,\bar{u}_n = \dfrac{Q}{Q_n + Q}\,\bar{\bar{u}}_n$	80, 81

Astatic Action.—The first action is defined by

$$P = 0, \qquad Q = -Q_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (70)$$

Inspection of Eq. 68 shows that $\delta T = 0$ when

$$u_0 = \frac{Q_n q_0}{V_0}, \quad u_n = \text{any value, all other parameters } u_m = 0 \ldots\ldots (71)$$

Since the parameter u_n may pass through a continuous range of values, defining a continuous range of shapes of the structure, the equilibrium is called neutral, and the action is described as buckling under the critical load $-Q = Q_n$. Since all other parameters remain zero except u_0, this buckling is called pure buckling or astatic action. The load $-Q$ is called an astatic load; the parameters $u_1, u_2, \cdots u_n, \cdots$ are called astatic parameters; and u_0 is called the orthostatic parameter of the astatic action. If T is a maximum by variation of some of the parameters, the equilibrium is unstable, though neutral by variation of u_n. Further examination[23] of Eq. 68 shows that if the quadratic expressions for V and q are written with mixed terms included, such as $V_{mn} u_m u_n$ and $q_{mn} u_m u_n$, knowledge of the existence of two astatic actions, one with $u_m =$ any value, $u_n = 0$ and the other with $u_m = 0$, $u_n =$ any value, at two different values of the astatic load, leads to the conclusion that $V_{mn} = q_{mn} = 0$. It follows that if the states of pure buckling can be ascertained, q and V can be written in the relatively simple forms of Eqs. 66 and 67; and thereby the nature of the astatic parameters is also ascertained.

Orthostatic Action.—The second action to be examined is defined by

$$P \neq 0, \qquad Q = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

Eqs. 68 and 69 give $u_0 = 0$ and the following value of u_n for $n = 1, 2, \cdots$:

$$\bar{u}_n = \frac{P\, p_n}{Q_n\, q_n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

The parameters are proportional to the load P; the same applies to the deformations and stresses, which are linear functions of the parameters. No buckling is involved; therefore this is the usual action dealt with in structural mechanics. In the terminology of the theory of buckling, this action, in which the astatic load is absent, is called orthostatic action. The load P is called the orthostatic load. Eq. 73 defines the values of the astatic parameters in the orthostatic action.

Relaxed Action.—In the third action to be examined the structure is assumed to have been modified by a relaxation of stiffness. The strain energy V in Eq. 67 is reduced in the relaxed structure by removing all terms except the first, so that now

$$V = \tfrac{1}{2} V_0\, u_0^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

It will be assumed that

$$P \neq 0, \qquad Q > 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

When the proper terms are omitted in Eq. 68 one finds

$$u_0 = -\frac{Q\, q_0}{V_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

and the following value of u_n for $n = 1, 2, \cdots$:

$$\bar{\bar{u}}_n = \frac{P\, p_n}{Q\, q_n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

---

[23] "Buckling of Elastic Structures," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. 85 (1922), p. 576, especially pp. 611–612.

Eq. 77 defines the values of the astatic parameters in the relaxed action. The equilibrium is stable, and Q is a stabilizing load.

Heterostatic Action.—In the fourth and last action to be considered the structure is assumed to have recovered its stiffness. Both the orthostatic and the astatic loads are present, that is,

$$P \neq 0, \qquad Q \neq 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

This general type of action is called heterostatic action; the combined load P, Q is a heterostatic load, with the orthostatic component P and the astatic component Q. By Eqs. 68 and 69 one finds u_0 as in Eq. 76, and for $n = 1, 2, 3, \cdots$:

$$u_n = \frac{P\,p_n}{(Q_n + Q)\,q_n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

A comparison of Eq. 79 with Eqs. 73 and 77 shows that

$$\frac{u_n}{\bar{u}_n} = \frac{Q_n}{Q_n + Q} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

and

$$\frac{u_n}{\bar{\bar{u}}_n} = \frac{Q}{Q_n + Q} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

When Q is positive, Eq. 80 defines the reduction factor of the astatic parameter u_n by transition from the orthostatic action to the heterostatic action under the influence of the stabilizing load Q; and Eq. 81 defines the reduction factor of the same parameter by transition from the relaxed action to the heterostatic action by restoration of the stiffness. When Q is negative, the factors in Eqs. 80 and 81 become magnification factors. It may be noted in passing that $\frac{Q}{Q_n}$ is the transition factor $\frac{\bar{u}_n}{\bar{\bar{u}}_n}$ by change from the relaxed to the orthostatic action.

Example.—A slender horizontal tension member bending under its own weight will serve as illustration. The ends are assumed to be hinged, and the end load central. The total horizontal tension is the stabilizing load Q. The weight, w per unit of length, is the orthostatic load. Assume that the cross section is constant, with area A and moment of inertia I. Let E = modulus of elasticity, l = length, x = distance measured from one end. Then the nth critical value of the astatic load $-Q$ is defined by Euler's formula

$$Q_n = \frac{n^2\,\pi^2\,E\,I}{l^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

and the deflections maintained by it are

$$y = u_n \sin \frac{n\,\pi\,x}{l} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (83)$$

in which u_n is a proper astatic parameter. As orthostatic parameter of the orthostatic action one may introduce the total shortening of the center line,

$u_0 = -\dfrac{Q\,l}{E\,A}$, which makes $q_0 = 1$. The parameter u_0 presents no difficulties in this problem.

In the relaxed action the member is changed into a cable, which deflects according to the law

$$-\frac{d^2y}{dx^2} = \frac{w}{Q} \qquad \text{(84)}$$

Eq. 84 may be rewritten so that the right side expresses a sum of corresponding effects in astatic actions, as follows:[24]

$$-\frac{d^2y}{dx^2} = \frac{4\,w}{\pi\,Q} \sum_{1,3,\ldots}^{n} \frac{1}{n} \sin \frac{n\,\pi\,x}{l} \qquad \text{(85)}$$

When the stiffness is restored, each term in the summation in Eq. 85 is multiplied by a reduction factor defined by Eqs. 81 and 82. After multiplying by $-E\,I$, one obtains in this way the bending moments in the heterostatic action,

$$M = \frac{4\,w\,l^2}{\pi^3} \sum_{1,3,\ldots}^{n} \frac{Q_1}{n\,(Q_n + Q)} \sin \frac{n\,\pi\,x}{l} \qquad \text{(86)}$$

The series in Eq. 86 converges and defines the stresses.

Eq. 86 may also be derived by way of the orthostatic action. When $Q = 0$,

$$\frac{d^4y}{dx^4} = \frac{w}{E\,I} = \frac{4\,w}{\pi\,E\,I} \sum_{1,3,\ldots}^{n} \frac{1}{n} \sin \frac{n\,\pi\,x}{l} \qquad \text{(87)}$$

After two integrations one finds the bending moment in the orthostatic action

$$\bar{M} = \frac{4\,w\,l^2}{\pi^3} \sum_{1,3,\ldots}^{n} \frac{1}{n^3} \sin \frac{n\,\pi\,x}{l} \qquad \text{(88)}$$

When Q is introduced, and the reduction factors are applied according to Eq. 80, Eq. 86 is reproduced.

The general theory may be applied to the problem in other ways. For example, the theory will furnish the series needed first, such as those in Eqs. 85 and 87; this is important for the more complicated problems in which the corresponding series are not simple trigonometric series. The computations may be made as follows: The contribution of the deflections $y = u_n \sin \dfrac{n\,\pi\,x}{l}$ to the path of the distributed load w (which takes the place of P in Eq. 68) is

$$p = p_n\,u_n = \int_0^l y\,dx = \frac{2\,l\,u_n}{n\,\pi} \qquad \text{(89)}$$

if n is uneven, and zero if n is even; and the corresponding contribution to the path of Q is

$$q = -\tfrac{1}{2}\,q_n\,u_n^2 = -\tfrac{1}{2} \int_0^l \left(\frac{dy}{dx}\right)^2 dx = -\frac{n^2\,\pi^2\,u_n^2}{4\,l} \qquad \text{(90)}$$

---

[24] See "A Short Table of Integrals," by B. O. Peirce, 2d Ed., Ginn & Co., 1910, formula 808.

The last two equations define p_n and q_n directly, and thereafter $\bar{u}_n$ through Eqs. 73 and 82. Thus one finds the deflections in the orthostatic action

$$y = \sum_{1,3,\ldots}^{n} \bar{u}_n \sin \frac{n \pi x}{l} = \frac{4 w l^4}{\pi^5 E I} \sum_{1,3,\ldots}^{n} n^{-5} \sin \frac{n \pi x}{l} \ldots\ldots\ldots (91)$$

The deflections in the heterostatic action are obtained by applying the reduction factor in Eq. 80 to each term in Eq. 91. Eq. 86 is reproduced easily by this method. Another route to the same result is to determine $\bar{\bar{u}}_n$ by Eq. 77, and thereby the deflections in the relaxed action; from these one finds the deflections in the heterostatic action by applying the reduction factor in Eq. 81 to each term in the series.

The method of complementary energy is applicable to problems of stabilizing loads through its applicability to astatic actions.

STIFFENING OF SUSPENSION BRIDGES

That a suspension bridge is stiffened by its own weight was brought out in an analysis published by Joseph Melan[25] in 1888. Leon S. Moisseiff, M. Am. Soc. C. E., developed the theory further for the design of the Manhattan Bridge (1909); and F. E. Turneaure,[26] Hon. M. Am. Soc. C. E., investigated this application and contributed to, and presented, the theory. Since then this principle of stiffening has become well appreciated in America; it has been utilized in the design of the great bridges, and has been discussed in a notable American technical literature on the subject.[25, 26, 27] The dead load has the character of a stabilizing load.

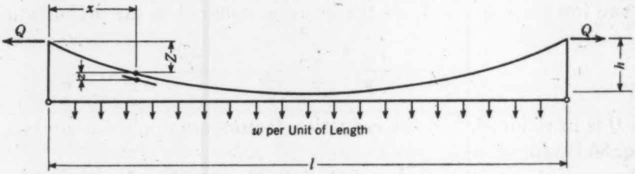


FIG. 4.—MAIN SPAN OF SUSPENSION BRIDGE

It is not intended here to present a full analysis of the stiffening of suspension bridges. It is desired only to show the applicability of the method of complementary energy to this problem through the theory of stabilizing loads and buckling.[28] The analysis therefore is limited to a simplified case, which is suggested in Fig. 4. The following actions are left out of account, as matters that can either be incorporated in a more extensive analysis by the same principles or be referred to independent supplementary analyses: elongations of the cable beyond the initial stretching; movements of the points of the cable at the tops of the towers; and elongations of the suspenders beyond the initial stretching. The suspenders are assumed to be spaced closely. The initial curve of the cable is assumed to be a parabola with a sag that is fairly small compared with the span. The following notation is used:

[28] The application of the theory of buckling of "the suspension bridge upside-down" to suspension bridges was suggested by H. M. Westergaard in a discussion, *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 1021.

x = horizontal coordinate.

Z = initial vertical coordinate, positive downward, of any point of the cable.

z = addition to Z by the change from the initial shape to the starting shape; with the restrictions imposed, z is also the starting deflection of the stiffening truss.

y = addition to z by the change from the starting shape to the final shape.

Y = total deflection, addition to Z, in a relaxed action in which neither the cable nor the truss contributes stiffness against bending.

η = total deflection, addition to Z, in the heterostatic action.

l = span.

$h = Z_{\max}$.

Q = horizontal component of the total tension in the cable; Q is interpreted as a measure of the stabilizing load.

Q_n = critical value of $-Q$ in an unstable astatic action.

w = uniformly distributed vertical load per unit of length; interpreted in this analysis as a reaction adjusting itself to Q as if it were a hydrostatic pressure.

P = orthostatic load.

K = force defined by Eq. 95.

M = sum of the bending moments in the stiffening truss and the cable at any value of x.

EI = measure of the combined stiffness of the stiffening truss and the cable against bending.

k = ratio defined by Eq. 117.

The initial parabolic curve of the cable has the equation

$$Z = 4\,h\,l^{-2}\,(l\,x - x^2) \quad \text{.....................(92)}$$

If the shape is changed by infinitesimal increments δZ, the potential energy of the uniformly distributed load w will be changed by the amount $-\,w \int_0^l \delta Z\,dx$. This amount is infinitesimal of second order because it is the total change of energy if the cable is unstiffened, and the parabola is the curve of equilibrium of the unstiffened cable. Therefore, when small quantities of second order, which will be without importance in the subsequent computations, are ignored, and under the simplifying restrictions that were imposed, and as long as the deflections z, y, Y, and η remain small, it can be asserted that

$$\int^l z\,dx = \int^l y\,dx = \int_0^l Y\,dx = \int_0^l \eta\,dx = 0 \quad \text{.........(93)}$$

The first task is to investigate the astatic actions at critical negative values of the loads in Fig. 4. Under the loads in Fig. 4, when the deflections are z, the combined bending moment in the cable and the truss is

$$M = \tfrac{1}{2} w (l x - x^2) - 4 Q h l^{-2} (l x - x^2) - Q z \quad \text{(94)}$$

It is expedient to introduce a force K defined by the equation

$$w = 8 (Q + K) h l^{-2} \quad \text{(95)}$$

Then

$$M = - Q z + 4 K h l^{-2} (l x - x^2) \quad \text{(96)}$$

and the increment of M by variation of the state of stress is

$$\delta M = - z \, \delta Q + 4 h l^{-2} (l x - x^2) \, \delta K \quad \text{(97)}$$

When z is chosen so that the supplementary deflections y are small, the relation of deformations to stresses

$$- \frac{d^2 y}{dx^2} = \frac{M}{E I} + \frac{d^2 z}{dx^2} \quad \text{(98)}$$

may be used with M as in Eq. 96.

The variation of the complementary energy may now be written:

$$\delta U = \int_0^l \left(\frac{M}{E I} + \frac{d^2 z}{dx^2} \right) dx \, \delta M$$

$$= \frac{1}{E I} \int_0^l \Big[- Q z + 4 K h l^{-2} (l x - x^2)$$

$$+ E I \frac{d^2 z}{dx^2} \Big] \Big[- z \, \delta Q + 4 h l^{-2} (l x - x^2) \, \delta K \Big] dx = 0 \quad \text{(99)}$$

This equation is converted into the following two, in which all integrations are from 0 to l:

$$E I \frac{\partial U}{\partial Q} = Q \int z^2 \, dx - 4 K h l^{-2} \int (l x - x^2) z \, dx$$

$$- E I \int z \frac{d^2 z}{dx^2} dx = 0 \quad \text{(100)}$$

$$E I \frac{\partial U}{\partial K} = - 4 Q h l^{-2} \int (l x - x^2) z \, dx + 16 K h^2 l^{-4} \int (l x - x^2)^2 \, dx$$

$$+ 4 E I h l^{-2} \int (l x - x^2) \frac{d^2 z}{dx^2} dx = 0 \quad \text{(101)}$$

Eqs. 100 and 101 are satisfied by the trivial solution $z = 0$, $K = 0$, $Q =$ any value. Non-trivial solutions exist, however. To find them, the following forms of z are suitable:

$$z = z_n \sin \frac{n \pi x}{l} \qquad \text{for } n = 2, 4, 6, \cdots \quad \text{(102)}$$

and

$$z = z_n \left(\sin \frac{n \pi x}{l} - \frac{1}{n} \sin \frac{\pi x}{l} \right) \qquad \text{for } n = 3, 5, 7, \cdots \ldots \ldots (103)$$

Both satisfy the requirement in Eqs. 93.

With z as in Eq. 102 the solution is

$$K = 0, \qquad - Q = Q_n = n^2 \pi^2 \frac{E I}{l^2}, \qquad \text{for } n = 2, 4, \cdots \ldots \ldots (104)$$

This result could have been found more easily, without invoking the method of complementary energy, by noting that Eq. 102 is the solution of Eq. 98 with $y = 0$, and with K and Q as in Eq. 104.

It is when the diagram of deflections is symmetrical, as by Eq. 103, that the method of complementary energy shows merit; because Eq. 103 will be close, although not identical, to an exact solution of Eq. 98 with $y = 0$. With z as in Eq. 103, Eqs. 100 and 101 become, after multiplication by $\frac{2}{l}$:

$$(1 + n^{-2})\, z_n^2\, Q + 32\, (n^{-1} - n^{-3})\, \pi^{-3}\, h\, z_n\, K$$
$$+ (n^2 + n^{-2})\, \pi^2\, E\, I\, z_n^2\, l^{-2} = 0 \ldots \ldots \ldots \ldots \ldots (105)$$

and

$$32\, (n^{-1} - n^{-3})\, \pi^{-3}\, h\, z_n\, Q + \frac{16}{15} h^2\, K = 0 \ldots \ldots \ldots \ldots (106)$$

Eq. 106 shows that K is proportional to Q but also proportional to the small ratio $\frac{z_n}{h}$; therefore K is a small supplementary force, although its influence may not be small. Elimination of K gives

$$[1 + n^{-2} - 960\, (n^{-1} - n^{-3})^2\, \pi^{-6}]\, Q = -\, (n^2 + n^{-2})\, \pi^2\, E\, I\, l^{-2} \ldots (107)$$

Since π^6 is very close to 960, and n^{-6} will be insignificant, the left side of Eq. 107 can be restated as $(1 + 2\, n^{-4})\, Q$. A further simplification, representing no significant loss of accuracy, reduces the solution to the form

$$- Q = Q_n = (n^2 - n^{-2})\, \pi^2 \frac{E I}{l^2}, \qquad \text{for } n = 3, 5, 7, \cdots \ldots \ldots (108)$$

Exact values of Q_n for $n = 3, 5, 7, \cdots$ can be found by solving Eq. 98 with $y = 0$ and M as in Eq. 94. It is found that these values are defined by the equations

$$\tan \alpha = \alpha + \frac{\alpha^3}{3} \ldots \ldots \ldots \ldots \ldots \ldots \ldots (109a)$$

and

$$Q_n = 4\, \alpha^2 \frac{E I}{l^2} \ldots \ldots \ldots \ldots \ldots \ldots \ldots (109b)$$

Furthermore, it is found that Eq. 108 gives a very close approximation to these exact values.

This completes the study of the astatic actions, but the goal is the heterostatic action. This goal may be reached either by the route of the orthostatic action or by the route of the relaxed action, in which all stiffness identified with elasticity is removed. The latter route is chosen.

The stabilizing load Q consists of the two horizontal forces Q in Fig. 4 and the distributed load w which is proportional to Q. An added vertical load is an orthostatic load if it requires no change of Q in the relaxed action. Let M_0 denote the bending moments that such a load would produce in a simple beam replacing the bridge. Simple considerations of statics show that in the relaxed action this load produces the deflections

$$Y = \frac{M_0}{Q} \dots\dots\dots\dots\dots\dots\dots\dots (110)$$

By referring to Eqs. 93 one obtains the condition

$$\int_0^l M_0 \, dx = 0 \dots\dots\dots\dots\dots\dots\dots\dots (111)$$

The loads in Fig. 5 are ascertained as two examples of orthostatic loads by noting that the moments which they would produce in a simple beam satisfy Eq. 111. It is observed further that any vertical load can be resolved into two component parts: one, an orthostatic load with moments satisfying Eq. 111; and the other a uniformly distributed load contributing to the astatic load Q. Therefore the function Y can be determined readily for any vertical load.

FIG. 5.—TWO EXAMPLES OF ORTHOSTATIC LOADS ON SUSPENSION BRIDGE

The next step is to express Y as a sum of functions representing deflections in astatic actions. The functions in Eqs. 102 and 103 are sufficiently close to the exact functions to serve this purpose. A suitable procedure is to expand the function Y into a Fourier series of the form

$$Y = \sum_{1,2,3,\dots}^{n} Y_n \sin \frac{n \pi x}{l} \dots\dots\dots\dots\dots\dots (112)$$

with the coefficients

$$Y_n = \frac{2}{l} \int_0^l Y \sin \frac{n \pi x}{l} \, dx \dots\dots\dots\dots\dots (113)$$

It may be convenient instead to begin by expressing the orthostatic load by a Fourier series, and then integrating twice to obtain M_0. In either case the series in Eq. 112 is obtained by a straight-forward and well-established process.

It is assured in advance that $\int_0^l Y\,dx = 0$. It follows that

$$Y_1 = -\sum_{3,\,5,\,\ldots}^{n} n^{-1}\,Y_n \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(114)$$

Then Eq. 112 may be rewritten in the desired form

$$Y = \sum_{2,\,4,\,\ldots}^{n} Y_n \sin\frac{n\,\pi\,x}{l} + \sum_{3,\,5,\,\ldots}^{n} Y_n\left(\sin\frac{n\,\pi\,x}{l} - n^{-1}\sin\frac{\pi\,x}{l}\right)\ldots(115)$$

The transition from the relaxed to the heterostatic action is made by applying the reduction factor in Eq. 81 to each term in Eq. 115, with Q_n defined by Eqs. 104 and 108. This reduction produces the deflections in the heterostatic action,

$$\eta = \sum_{2,\,4,\,\ldots}^{n} \frac{Q}{Q_n + Q}\,Y_n \sin\frac{n\,\pi\,x}{l}$$

$$+ \sum_{3,\,5,\,\ldots}^{n} \frac{Q}{Q_n + Q}\,Y_n\left(\sin\frac{n\,\pi\,x}{l} - \frac{1}{n}\sin\frac{\pi\,x}{l}\right)\ \ldots\ldots\ldots(116)$$

By introducing the notation

$$k = \frac{Q\,l^2}{\pi^2\,E\,I}\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(117)$$

and referring to Eqs. 104 and 108, which define the critical values Q_n of $-Q$, the final deflection, η in Eq. 116, can be restated in either of the following two forms:

$$\eta = -\sin\frac{\pi\,x}{l}\sum_{3,\,5,\,\ldots}^{n} \frac{k}{n(n^2 - n^{-2} + k)}\,Y_n$$

$$+ \sum_{2,\,4,\,\ldots}^{n} \frac{k}{n^2 + k}\,Y_n \sin\frac{n\,\pi\,x}{l} + \sum_{3,\,5,\,\ldots}^{n} \frac{k}{n^2 - n^{-2} + k}\,Y_n \sin\frac{n\,\pi\,x}{l}\ldots(118)$$

or,

$$\eta = Y + \sin\frac{\pi\,x}{l}\sum_{3,\,5,\,\ldots}^{n} \frac{n^2 - n^{-2}}{n(n^2 - n^{-2} + k)}\,Y_n$$

$$- \sum_{2,\,4,\,\ldots}^{n} \frac{n^2}{n^2 + k}\,Y_n \sin\frac{n\,\pi\,x}{l} - \sum_{3,\,5,\,\ldots}^{n} \frac{n^2 - n^{-2}}{n^2 - n^{-2} + k}\,Y_n \sin\frac{n\,\pi\,x}{l}\ldots(119)$$

After a certain value of n the series in Eq. 118 converge more rapidly than those in Eq. 119. For numerical computation the choice between the two formulas depends on the values of k and Y_n and on the accuracy that is desired.

INFLUENCE OF STABILIZING LOADS ON VIBRATIONS

A stabilizing load stiffens a structure. Therefore it will tend to reduce the periods of free vibration.

A mode of free vibration is characterized by the condition that all the significant deformations are proportional at each instant to a single parameter v which varies with the time t according to the law $v = u \cos \omega_n t$; u may have any value, is independent of t, and is a parameter corresponding to v but defining the extreme deformations.

It happens in some significant cases that the parameter u can be taken as any one of the astatic parameters u_n in Eq. 68. Then, by referring to Eq. 68, it will be seen that the part of the potential energy that varies during the vibration is $\frac{1}{2}(Q_n + Q)\, u_n^2 \cos^2 \omega_n t$. Since the velocities are proportional to $\omega_n u_n \sin \omega_n t$, the kinetic energy can be written as $\frac{1}{2} K_n \omega_n^2 u_n^2 \sin^2 \omega_n t$. Constancy of the combined potential and kinetic energy requires that

$$K_n \omega_n^2 = Q_n + Q \qquad (120)$$

If the stabilizing load Q is removed without changing the masses, ω_n and the corresponding period $t_n = \dfrac{2\pi}{\omega_n}$ will assume different values ω_{0n} and t_{0n}. Eq. 120 shows that the relations of the values are

$$\frac{t_n^2}{t_{0n}^2} = \frac{\omega_{0n}^2}{\omega_n^2} = \frac{Q_n}{Q_n + Q} \qquad (121)$$

That is, in the transition from a free vibration without the stabilizing load to one with the stabilizing load a reduction factor is applied to the square of the period equal to the reduction factor in Eq. 80, representing the transition from the orthostatic action to the heterostatic action under the stabilizing load Q.

FREE VIBRATIONS OF A SUSPENSION BRIDGE

While the astatic actions of a suspension bridge may be visualized by imagining gravity reversed or the bridge turned upside down, correspondingly, the free vibrations without stabilizing loads may be visualized by imagining gravity removed temporarily or the bridge merely keeled over so that cable and stiffening truss are placed in a horizontal plane.

The discussion will be limited again to the simplified case that has been under consideration. Furthermore, only vibrations in the plane of the cable and stiffening truss will be considered; and energies due to components of velocity in the direction of the span will be assumed to be relatively so insignificant that they can be ignored. Then the modes of vibration will be represented adequately by Eqs. 102 and 103. When the procedure leading to Eq. 57 is applied to Eq. 103, one finds that in the modes of $n = 3, 5, 7, \cdots$ the bending moments due to the load $w\,z$ are represented not exactly but with good approximation by the formula

$$X = \frac{w\, u_n\, l^2}{n^2 \pi^2} \left(\sin \frac{n \pi x}{l} - \frac{1}{n} \sin \frac{\pi x}{l} \right) \qquad (122)$$

By referring to Eq. 57, one finds, for $n = 3, 5, 7, \cdots$,

$$\omega_{0n}^2 = -\frac{\displaystyle\int X \frac{d^2 z}{dx^2}\, dx}{\displaystyle\int \frac{X^2\, dx}{E\, I\, g}}$$

$$= \frac{n^2\, \pi^4\, E\, I\, g \displaystyle\int_0^l \left(\sin \frac{n\, \pi\, x}{l} - \frac{1}{n} \sin \frac{\pi\, x}{l} \right) \left(n^2 \sin \frac{n\, \pi\, x}{l} - \frac{1}{n} \sin \frac{\pi\, x}{l} \right) dx}{w\, l^4 \displaystyle\int_0^l \left(\sin \frac{n\, \pi\, x}{l} - \frac{1}{n} \sin \frac{\pi\, x}{l} \right)^2 dx}$$

$$= \frac{(n^6 + n^2)\, \pi^4\, E\, I\, g}{(n^2 + 1)\, w\, l^4} \ldots\ldots\ldots\ldots\ldots\ldots (123)$$

or, by substitution from Eq. 108 and with a further permissible approximation,

$$\omega_{0n}^2 = \frac{n^2\, \pi^2\, g}{(1 + n^{-2} - 2\, n^{-4})\, w\, l^2}\, Q_n \qquad \text{for } n = 3, 5, 7, \cdots \; \ldots . (124)$$

A similar but simpler computation based on Eq. 102 gives

$$\omega_{0n}^2 = \frac{n^2\, \pi^2\, g}{w\, l^2}\, Q_n \qquad \text{for } n = 2, 4, 6, \cdots \; \ldots\ldots\ldots (125)$$

When the suspension bridge is again placed in its natural position and gravity contributes stiffness, the values of ω_{0n}^2 in Eqs. 124 and 125 will be increased to ω_n^2 in accordance with Eq. 121 by replacing the factors Q_n by $Q_n + Q$. Thereafter the periods of free vibration are obtained as $t_n = \dfrac{2\,\pi}{\omega_n}$. With the critical loads Q_n substituted from Eqs. 104 and 108, and the ratio k introduced from Eq. 117, the periods of free vibration become

$$t_n = \frac{2\, l^2}{n\, \pi} \sqrt{\frac{w}{(n^2 + k)\, E\, I\, g}} \qquad \text{for } n = 2, 4, 6, \cdots \; \ldots\ldots (126)$$

and

$$t_n = \frac{2\, l^2}{n\, \pi} \sqrt{\frac{(1 + n^{-2} - 2\, n^{-4})\, w}{(n^2 + n^{-2} + k)\, E\, I\, g}} \qquad \text{for } n = 3, 5, 7, \cdots \; \ldots . (127)$$

CONCLUSION

It has been shown that the method of complementary energy can be applied with advantage to a variety of problems in structural statics and dynamics.

DISCUSSION

I. K. SILVERMAN,[29] ASSOC. M. AM. SOC. C. E. (by letter).—The ideas presented in this paper throw a great deal of light on a concept that seems to have become axiomatic in many minds. This concept is one that deals with the economy of Nature, and it is expressed in textbooks dealing with the theory of structures by means of the "Principle of Least Work." Perhaps it is because the engineer, in dealing with forces, has come to have a respect for the way Nature behaves. The behavior of liquids, the action of falling bodies, the structure of organic materials such as bones and feathers,[30] the apparent minimal surfaces that may be obtained with thin films, cells of honeycombs, etc., all seem to be conclusive evidence of the economy of Nature.

It is a far cry from the Ptolemaic concept of the universe to the Principle of Least Work of modern structural analysis, but the conflict between the theological and mechanical concepts of the universe, which raged around the Ptolemaic theory, imparted a metaphysical twinge to the ideas of the philosophers who followed Galileo.

In their studies of the phenomena of Nature the investigators of the seventeenth and eighteenth centuries attempted to explain them from the inherent perfection of the Creator. It is not strange, therefore, to find the concepts of minimum arising from the efforts of the philosophers of this age to explain the universe. So great has been the influence of these precursors of modern science that their "minimum principles" have come down through the centuries to be included in modern textbooks with even the argument of the wisdom of the Creator in calling for economy in Nature. Such is the background of the principle of the minimum in the theory of structures.

Jules Henri Poincaré declared that any generalization which is based on experimental results has no right to be called a principle, and an examination of the assumptions which led to Castigliano's second theorem and thence to what is generally, but incorrectly, called the Principle of Least Work will bear this out. The basic assumptions are as follows, as applied to engineering structures:

1. The deformations produced are infinitesimal and thus it follows that the law of superposition holds; and
2. A linear relation exists between the forces and displacements.

From these two assumptions the energy stored in a body can be expressed as a quadratic in the forces or the displacements. Castigliano's first theorem follows: The partial derivative of the expression for energy containing the forces with respect to any force gives the displacement of the force in the direction it acts; and, for those forces which do not move because of their geometrical or kinematical restraints, the partial derivatives are zero. This latter result can be expressed as a theorem interpreting the vanishing of the derivative as a condition for a minimum. This theorem of "minimum" will not hold for the cases in which (*a*) the law of superposition is no longer true, and (*b*) the material does not follow Hooke's law.

---

[29] Care, Panama Canal, Canal Zone.

[30] "The Science of Mechanics," by E. Mach, The Open Court Publishing Co., Chicago, Ill., 1893, p. 452.

These conditions are purely experimental, and in the light of Poincaré's specifications the term "principle" is inadmissible. Most of the materials used in structural engineering may be considered to satisfy the conditions under which the theorem holds, and the results obtained in practise agree essentially with those predicted by the application of the theorem.

The author has introduced a new term, complementary energy, which is certainly not of anthropomorphic origin. It is nothing more than a mathematical expression involving stresses or forces which, upon differentiation with respect to the stress or force, gives the corresponding strain or displacement. When the forces involved are constrained kinematically or geometrically the ensuing derivative is set equal to zero, which is interpreted as a minimum. The author has shown that in the case of Hooke's law "complementary energy" coincides with "elastic energy."

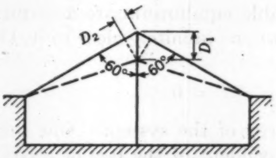

FIG. 6

FIG. 7

The only check on the results obtained by using either the "law of least complementary energy" or the "law of least elastic energy" is a geometrical one. In both cases the equations of equilibrium are first applied and when dealing with a statically indeterminate structure a "minimum principle" is used to determine the statically indeterminate quantities. In the last analysis the results obtained can be checked only by noting that the conditions of continuity are preserved. Thus the three solutions for S_1 of Fig. 2(*a*) can be shown to be correct as follows:

From Fig. 6 the deformation D_1 is connected with the deformations D_2 and D_3 by the following equation:

$$D_1 = \frac{D_2}{\cos 60^\circ} = 2\,D_2 \ldots\ldots\ldots\ldots\ldots\ldots (128a)$$

For $P < 3\,C$,

$$D_1 = (P - X)\,k = 2\,k\,X = 2\,D_2; \quad \text{and} \quad X = \frac{P}{3} \ldots\ldots (128b)$$

For $3\,C < P < 5\,C$,

$$D_1 = 2\,k\,(P - X - C) = 2\,k\,X = 2\,D_2; \quad \text{and} \quad X = \frac{P - C}{2} \ldots (128c)$$

and, for $P > 5\,C$,

$$D_1 = 2\,k\,(P - X - C) = 4\,k\,(X - C) = 2\,D_2; \quad \text{and} \quad X = \frac{P + C}{3} \ldots (128d)$$

The fundamental character of a solution based on consistent deflections is apparent; but it must be admitted that a solution based on a "minimum" principle as presented by the author will prove more attractive to analysts because of its economy of thought.

Stability Problems.—The essential feature in the study of stability problems is that the structure in question is assumed to have a geometrical configuration entirely different from its original state. The equations of equilibrium are set up from this strained state rather than from the unstrained state as is done in all other problems of equilibrium. The question then becomes: What must be the value of the forces so that the strained state may be maintained? Two general methods are available that can be shown to be identical.

The first method involves the problem of the elastica—that is, the solution of the differential equation that describes the possible states of equilibrium. The second method, the energy method, is based on the fact that, for unstable equilibrium, the potential energy of a system is a maximum and any virtual variation from that state involves a decrease in potential energy. The criterion by which the conditions of unstable equilibrium are determined is that, in the transition from the actual state to one infinitely close to it, the variation of the potential energy is zero; that is,

$$\delta T = 0 \dots\dots\dots\dots\dots\dots\dots\dots (129)$$

in which T is the potential energy of the system. One important feature of this statement is that it is independent of the law of elasticity and holds for large displacements.

Instead of using the potential energy of the structure, the author has substituted for it a "complementary energy" and claims superiority of the method of "complementary energy" over the potential energy by showing that, by the use of Eq. 23, based on "complementary energy," a closer value to the buckling load can be obtained than by using Eq. 27, which is based on potential energy.

The reason for this apparent superiority lies in the fact that the author has satisfied all boundary conditions by using the expression $M = P z$ for the moment at any point whereas Eq. 27 utilizes the more general term $M = E I \frac{d^2 z}{dx^2}$. When Eq. 27 is to be used the approximating function must satisfy all the boundary conditions and using Eq. 24 would naturally give a poor result. The Timoshenko variant takes this fact into account by writing

$$P z = M = E I \frac{d^2 z}{dx^2} \dots\dots\dots\dots\dots\dots (130)$$

If an expression that satisfies all boundary conditions is used, Eq. 27 furnishes a more accurate result than does Eq. 23 when Eq. 24 is used. For example, assume

$$z = c \,(l^3 x - 2\, l\, x^3 + x^4) \dots\dots\dots\dots\dots\dots (131)$$

which satisfies all boundary conditions. From Eq. 27

$$P = \frac{168}{17} \frac{E I}{l^2} = 9.8824 \frac{E I}{l^2}.$$

Substituting this expression in Eq. 23 or Eq. 28 will yield as a result

$$P = \frac{306}{31}\frac{E\,I}{l^2} = 9.8797\,\frac{E\,I}{l^2}\ldots\ldots\ldots\ldots\ldots\ldots(132)$$

As a matter of fact Eq. 27 has a marked superiority over Eq. 23 in that it is perfectly general and will hold under all boundary conditions, whereas Eq. 23 will have to be modified according to the boundary conditions. Consider the case shown in Fig. 7.

Assume a starting shape

$$z = c\,(3\,l\,x^2 - x^3)\ldots\ldots\ldots\ldots\ldots\ldots(133)$$

which satisfies all boundary conditions. The exact solution for this case is $P = \frac{\pi^2}{4}\frac{E\,I}{l^2}$. From Eq. 27, $P = 2.5\,\frac{E\,I}{l^2}$, whereas Eq. 23 gives the impossible value of $P = -\frac{14}{11}\frac{E\,I}{l^2}$. Evidently Eq. 23 must be modified to take the free end into account.

Eq. 27 was derived by equating Eq. 26 to zero, but an equivalent and (in the writer's opinion) more fundamental expression may be derived by the application of Eq. 129.

From Eq. 26

$$T = \frac{1}{2}\int_0^l \left[E\,I\left(\frac{d^2z}{dx^2}\right)^2 - P\left(\frac{dz}{dx}\right)^2\right] dx\ldots\ldots\ldots\ldots(134)$$

The variation of this integral is a problem in the Calculus of Variations, and on performing the variation the following result is obtained:

$$\delta T = \int_0^l \left[E\,I\,\frac{d^4z}{dx^4} + P\,\frac{d^2z}{dx^2}\right]\delta z\,dx - \left[\left(P\,\frac{dz}{dx} + E\,I\,\frac{d^3z}{dx^3}\right)\delta z\right]_0^l$$

$$+ E\,I\left[\frac{d^2z}{dx^2}\,\delta\left(\frac{dz}{dx}\right)\right]_0^l = 0\ldots\ldots\ldots\ldots\ldots\ldots(135)$$

The terms in the brackets are called "the terms at the limits," and when they are zero Eq. 135 becomes

$$\int_0^l \left[E\,I\,\frac{d^4z}{dx^4} + P\,\frac{d^2z}{dx^2}\right]\delta z\,dx = 0\ldots\ldots\ldots\ldots\ldots(136)$$

Since the variation δz is arbitrary, Eq. 136 is fulfilled when

$$E\,I\,\frac{d^4z}{dx^4} + P\,\frac{d^2z}{dx^2} = 0\ldots\ldots\ldots\ldots\ldots\ldots(137a)$$

Eq. 137*a* may be integrated to

$$E\,I\,\frac{d^2z}{dx^2} + P\,z = 0\ldots\ldots\ldots\ldots\ldots\ldots(137b)$$

which is nothing more than the differential equation given by Leonhard Euler. From this demonstration may be seen the connection between the problem of the elastica and the energy method.

The approximate solution of all problems in mechanics based on the variation of an integral can be simplified greatly, as follows: When the boundary conditions are such that the "terms at the limits" are zero, Eq. 135 becomes Eq. 136. In general, Eq. 136 may be written[31] as

$$\int_0^l [\text{Differential equation of equilibrium}] \times [\text{Virtual change of the function describing the state of equilibrium}]\, dx = 0 \quad \text{(138)}$$

When the "terms at the limits" are not zero an equation of the form of Eq. 135 must be dealt with. It must be remembered that Eq. 135 is the result of the variation of the integral of potential energy of a straight column subjected to end loads. Any other condition of loading will require a slightly different expression.

Consider the case shown by Fig. 3(*a*). The application of Eq. 135 to this case is as follows:

Since the ends are held, the terms at the limits vanish leaving Eq. 136 or 138. Assuming the value of z in Eq. 131, which satisfies all boundary conditions:

$$\frac{dz}{dx} = c\,(l^3 - 6\,l\,x^2 + 4\,x^3);\quad \frac{d^2z}{dx^2} = 12\,c\,(x^2 - l\,x) \quad \text{(139a)}$$

$$\frac{d^3z}{dx^3} = 12\,c\,(2\,x - l);\quad \frac{d^4z}{dx^4} = 24\,c \quad \text{(139b)}$$

and,

$$\delta z = \delta c\,(l^3\,x - 2\,l\,x^3 + x^4) \quad \text{(139c)}$$

Substituting in Eq. 136

$$\int_0^l [E\,I\,24\,c + 12\,P\,c\,(x^2 - l\,x)][l^3\,x - 2\,l\,x^3 + x^4]\,\delta c\,dx = 0 \quad \text{(140)}$$

Performing the integrations it will be found that

$$P = \frac{168}{17}\,\frac{E\,I}{l^2} \quad \text{(141)}$$

The differential equation of the strained column is given by Eq. 137*b*. From Eq. 138

$$\int_0^l \left[E\,I\,\frac{d^2z}{dx^2} + P\,z \right] \delta z\,dx = 0 \quad \text{(142)}$$

Substituting Eqs. 139 and performing the integrations will lead to

$$P = \frac{306}{31}\,\frac{E\,I}{l^2} \quad \text{(143)}$$

For the case shown by Fig. 7, Eq. 138 cannot be used and Eq. 135 including the "terms at the limits" must be used.

The same general method can be applied to vibrating systems.[32]

---

[31] "Eine Wichtige Vereinfachung der Methode von Ritz zur angenaherten Behandlung von Variationsproblemen," by H. Hencky, *Zeitschrift für angew. Mathematik und Mechanik*, Vol. 7, 1927, p. 80.

[32] "On Forced Pseudo-Harmonic Vibrations," by I. K. Silverman, *Journal of the Franklin Institute*, June, 1934, p. 743.

One point which should be emphasized in the foregoing approximations is that the critical loads and their analogous quantities in vibrating systems are always larger than the actual values and, therefore, are necessary but not sufficient magnitudes. Therefore, these approximate values are on the unsafe side and other methods[33] should be used to determine the lower limit.

Fundamentally there is no difference between the method presented by the author as expressed by Eq. 11 and that as expressed by Eq. 138. The writer believes that the differential equation or the energy expression of a given problem can be "set up" with greater ease than the deflections, displacements, and changes of curvature required by Eq. 10. Furthermore, all reference volumes on the theory of structures present the general theory of equilibrium via the differential equation and the investigator will find Eq. 138 quite easy to handle.

The method based on Eq. 138 also may be used in the approximate solution of problems of stable equilibrium (for example, in the determination of the deflections of beams, etc.). One important problem to which it has been applied is that dealing with the action of a suspension bridge subjected to lateral forces and to the determination of the natural frequencies of this type of structure when vibrating in a horizontal plane.

Under the action of a uniform wind load the deflection of a suspension bridge can be expressed as

$$\delta = \sum_{n=1,3,5\cdots} \frac{a_n\, l^4}{E\, I} \sin \frac{n\, \pi\, x}{l} \qquad \text{.................. (144)}$$

The moment and shear in the horizontal system may be determined from $M = E\, I \frac{d^2\delta}{dx^2}$; and shear $= E\, I \frac{d^3\delta}{dx^3}$. Eq. 138 may be used to determine the values of a_n. A set of simultaneous equations is obtained given by the general formula

$$a_n\, [(\pi\, n)^4 A_1 + (\pi\, n)^2 A_2 - A_3] - \sum_i a_i \frac{A_4\, (n\, i)^5}{(n - i)^2\, (n + i)^2}$$
$$= \frac{A_5}{(n\, \pi)^3} - \frac{A_6}{n\, \pi}, \qquad \text{for } n = 1, 3, 5, \cdots \text{ .... (145)}$$

in which i may have any odd integral value except n, depending upon the number of terms assumed in the series, Eq. 144; and A_1 to A_6 are constants of the structure and loading. Thus a direct solution is furnished by use of Eq. 138 to replace the tedious trial and error solution now available.[34]

George R. Rich,[35] M. Am. Soc. C. E. (by letter).—Dean Westergaard has prepared a valuable and interesting paper which, for maximum benefit, should be read as a sequel to his earlier paper on the "Buckling of Elastic Structures,"[36] from which the somewhat formidable terms "orthostatic action,"

---

[33] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., 1936, p. 84; also "Rayleigh's Principle," by G. F. J. Temple and W. G. Bickley, Oxford Press, 1933, p. 29 and p. 72.

[34] "Suspension Bridges Under the Action of Lateral Forces," by Leon S. Moisseiff and Frederick Lienhard, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1080.

[35] Chf. Design Engr., TVA, Knoxville, Tenn.

[36] "Buckling of Elastic Structures," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 576.

"astatic action," and "heterostatic action" emerge as the more familiar expressions "simple stress or bending," "pure buckling," and "mixed buckling."

In determining critical buckling loads or natural periods of vibration, it appears from the examples adduced by the author that the method of complementary energy affords much greater latitude than the Rayleigh method in the selection of functions to represent the deflected elastic line. This is particularly striking in the author's use of parabolic loci in the cases of the buckling of hinged-end columns and the lateral vibration of prismatic beams. In the Rayleigh type of investigation, parabolic curves do not ordinarily yield dependable results for the reason that the resultant expression for curvature of the member, $\frac{d^2z}{dx^2}$, is a constant, whereas the curvature should vary with the bending moment. In problems similar to the analysis of vibrations in suspension bridges, in which the choice of functions naturally gravitates to certain standard trigonometric forms or Fourier expressions, the Rayleigh method appears to have the advantages of greater simplicity and directness without any considerable sacrifice of accuracy.

For example, Eqs. 125 and 126 may be verified exactly, Eq. 124 checked very closely, and Eq. 127 checked within 10% by direct substitution, in a single operation, of the functions

$$z = z_n \sin \frac{n \pi x}{l} \sin \omega t, \qquad \text{for } n = 2, 4, 6, \cdots \ldots\ldots\ldots (146a)$$

and

$$z = z_n \left(\sin \frac{n \pi x}{l} - \frac{1}{n} \sin \frac{\pi x}{l} \right) \sin \omega t, \qquad \text{for } n = 3, 5, 7, \cdots \ldots\ldots (146b)$$

in the standard Rayleigh form of the energy equation:

$$\int_0^l \frac{w}{2\,g} \left(\frac{dz}{dt} \right)^2 dx = \int_0^l \frac{E\,I}{2} \left(\frac{d^2z}{dx^2} \right)^2 dx + \int_0^l \frac{Q}{2} \left(\frac{d^2z}{dx^2} \right) z\, dx \ldots (147)$$

In fact, Eqs. 125 and 126 may be verified exactly by using the somewhat rougher form of Rayleigh expression:

$$\int_0^l \frac{w}{2\,g} \left(\frac{dz}{dt} \right)^2 dx = \int_0^l \frac{E\,I}{2} \left(\frac{d^2z}{dx^2} \right)^2 dx + \int_0^l \frac{Q}{2} \left(\frac{dz}{dx} \right)^2 dx \ldots (148)$$

in which the term $\int_0^l \frac{Q}{2} \left(\frac{dz}{dx} \right)^2 dx$ reflects the assumption that the increased length of cable due to the vibratory motion is equal to the increased length of elastic line of the deflecting stiffening truss. In using the Rayleigh method for this problem, the x-axis is taken as the undeflected axis of the stiffening truss, and all ordinates z are measured to the deflected elastic line of the truss. No ordinates are measured to the cable. The functions adopted for z simply represent the idea that the stiffening truss deflects during vibration into either an even number of alternating equal bay waves or an odd number of alternating unequal bay waves, the configurations in either case being such that the net departure of the cable during vibratory motion from the parabolic form in equilibrium under the dead load is a minimum. This action is implied by

Eqs. 93. In addition, these functions represent the familiar normal modes in which the oscillations of all elements of the elastic system are either in phase or in opposition, and the functions chosen have the convenient conjugate orthogonal property

$$\int \sin m\,x \sin n\,x\,dx = 0, \qquad \text{for } m \neq n \text{............} \quad (149)$$

In this connection, it is recognized that the author's primary purpose is to give examples of sufficient variety to demonstrate the power and range of the method of complementary energy. He is well aware, of course, that in certain instances alternative methods may prove equally convenient, as is shown by his statement that the problem of buckling of a thin circular disk supported at the edges and loaded by a normal edge load may be solved with equal ease by the standard method of attack using Bessel functions.

Dean Westergaard has rendered continued service to practicing engineers by demonstrating the great economy of time and labor, and the penetrating insight into structural action, that are afforded by the use of the more incisive methods of advanced analysis. Without attempting the mastery of existence theorems, reasonable facility in the use of the variational principles may be acquired for a surprisingly small expenditure of time; and, as remarked by Lord Rayleigh sixty years ago,[18] the difficulty in connection with Fourier series lies not in its practical physical applications, but only in a rigorous demonstration of what the professional mathematician means by the statement that the expansion represents the function "almost everywhere."

R. V. **SOUTHWELL**,[37] **ESQ.** (by letter).—By this communication the writer wishes to record his appreciation of Dean Westergaard's very clear presentation of the "Method of Complementary Energy." The use of a quasi-energy function, defined as in Eq. 9, was propounded in one of the contributions to a symposium of engineering mechanics held at Ann Arbor, Mich., in the summer of 1935. The writer does not remember, however, that the notion was then attributed by any speaker to Engesser, and he was not aware that it had been propounded already. It must be of interest to all teachers who are concerned to understand the fundamentals of stress-strain theory.

Whether it will have equal appeal to the engineer whose first concern is to calculate correctly, only time can show. Use has so familiarized the concepts of kinetic and potential energy that as an investigator one is kept straight, so to speak, in one's working by a kind of physical intuition, and as a teacher one is likely to regard those concepts as natural and easy. It is salutary, perhaps, to find how groping are one's first attempts to use the complementary notion: One may thereby be made more sympathetic to the difficulties of students! Clearly, time must be found for a serious attempt to master the new technique, and to assess its sphere of usefulness.

Meanwhile, the writer can offer only one comment in regard to the comparison of methods given under the headings "Buckling of Column with Hinged Ends" and "Application to Vibration of Beams." Dean Westergaard has given two examples in which the error resulting from a use of Rayleigh's principle exceeds 20%. The writer suggests that these examples are not really fair to the principle, for the reason that modes such as Eqs. 24 and 61 are excluded (tacitly) in the argument by which it is derived. That argument is based on the concept of conservation of energy, and a formula such as Eq. 27 presumes that no energy can enter or leave the system. A mode in which both slope and curvature are non-zero at the ends of a strut, however, must entail there either input or output of energy. Neglecting this "leakage," it is not surprising that one should obtain seriously inaccurate results. Similar remarks apply to the second example.

---

[37] Prof. of Eng. Science, Oxford Univ., Oxford, England.

The writer's reason for emphasizing this point is that an analogous condition for close accuracy should presumably be recognized when the complementary method is used. It would be worth while to examine whether this is so, and whether (for example) it excludes the use of a mode as shown in Fig. 3(*b*). In fact, when two methods have such close similarity, it is to be expected that every precaution that must be taken in using the first has its analogue in a precaution that must be taken in using the second. Provided that such precautions have been stated and are generally recognized, the method of complementary energy seems likely to play an important part in the study of plastic distortions, where the notion of elastic strain-energy has such limited utility.

H. M. WESTERGAARD,[38] M. AM. SOC. C. E.—The writer is indebted to Mr. Rich and Professor Southwell for their comments, but he cannot accept the arguments presented by Mr. Silverman.

For example, Mr. Silverman notes that Eq. 23 does not apply well to a cantilever column with the axis of x along the original center line; but one would not write Eq. 23 for that case. The bending moment for the starting shape in this case is not $P\,z$ but $P(z - z_{\max})$, which, with z as in Eq. 133, gives

$$P = \frac{42}{17}\frac{E\,I}{l^2} \qquad (150)$$

The value in Eq. 150 differs only by 0.13% from the true value,

$$P = \frac{\pi^2}{4}\frac{E\,I}{l^2} \qquad (151)$$

and is, in fact, a satisfactory result. Mr. Silverman uses the calculus of variations to derive Eq. 137*b*, but it should be observed that this equation does not apply to the cantilever column with the axis of x along the original center line. In Mr. Silverman's Eq. 138, "Differential equation of equilibrium" is a meaningless factor. If one guesses that "one side of a differential equation" is intended instead of "differential equation," the statement in Eq. 138 still would require a clear explanation of the relation of the mathematical forms to the actualities of structural mechanics. Mr. Silverman's Eq. 145 for vibrations of a suspension bridge contains undefined constants and is only a vague suggestion of a solution. His comment that Castigliano's laws are not principles can be dismissed as untenable. The entire discussion by Mr. Silverman can be dismissed; it throws no light on the method of complementary energy.

---

[38] Dean, Graduate School of Eng., and Gordon McKay Prof. of Civ. Eng., Harvard Univ., Cambridge, Mass.

Referring to the understanding comments by Mr. Rich, the writer only wishes to state that he does not advocate the supplanting of other methods by the method of complementary energy; the writer does suggest the inclusion of the method of complementary energy among the tools of structural analysis.

The remarks by Professor Southwell on the importance of avoiding leakage in the account of energy and on the nature of analogies are much to the point. Illustrations surely can be found in which there is greater danger of leakage in the account of the complementary energy than in the corresponding account of the energy. As to analogies, it should be mentioned that they exist in different degrees. In the basic equations involving the energy T and the complementary energy U, in changing from the use of T to the use of U, the statical terms, load P, stress S, and reaction R, are replaced in order by the geometrical terms, path r of a reaction, deformation D, and path p of a load, and vice versa. This statement applies not only to the equations expressing the fact that T and U are minima when the quantities P and r are constant, but applies also to two further equations which can be derived from the principles of minimum and represent the extension of Castigliano's first and second laws. These two further equations apply when the quantities r are admitted as variables defining T, or the quantities P are admitted as variables defining U; and they are:

$$R = \frac{\partial T}{\partial r} \quad \text{.........................} (152)$$

and

$$p = \frac{\partial U}{\partial P} \quad \text{.........................} (153)$$

Thus an analogy is established in which there is a one-to-one correspondence of terms in two pairs of basic equations, but this analogy has not been extended to such a degree of completeness that, given a structure, one could always visualize an analogous structure in which the statical quantities of the original structure appear as geometrical quantities, and vice versa. Some of the well-known specific analogies possess this degree of completeness; for example, the soap-film analogy by which torsional stresses are represented by slopes of a film (which is a structure of a kind); or the analogy by which curvatures of a plate represent a two-dimensional state of stress in the plane of a slice. The comments made by Professor Southwell suggest the observation that the old field of structural mechanics is still open for profitable new exploration.

SOME ECONOMICS OF AIRPORTS

By W. WATTERS PAGON,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLIAM E. RUDOLPH, DONALD M. BAKER, AND W. WATTERS PAGON.

SYNOPSIS

So much has been written regarding the location and the engineering design of airports that the writer has chosen rather to discuss some of the economic factors relating to the growth in size and in density of use of existing ports. This paper also deals largely with ports intended for transport planes. Until recently, the number of airports had reached and declined from a saturation point. Under the stimulus of war there is now (1941) a renewed growth, and a higher saturation value, although at present there is no reliable indicator to serve as a guide. For example, many state planning bodies are compiling lists of airports to be built progressively as the demand requires, and these will be correlated into a nation-wide plan; but the problem facing the present-day designer is primarily one of improvement and enlargement of present facilities.

GROWTH OF AIRPLANE USES

***The Entire Country.*—Naturally the first statistical indicator is the growth in use of planes, and for determining this growth the designer must rely on the rates of growth of other means of transportation. Such means fall roughly into two classes: (*a*) The common carrier, and (*b*) the private conveyance. Indicators for these classes cannot be determined upon comparable bases, for lack of detailed information, but they will be set up from available information and utilized to the extent of their evident limitations.**

In order to correlate such widely different sources of data one may adopt a Pearl biometric type of curve as indicative of growth of all means of transportation, as well as of biometric growth. Let:

f = numerical factor used to multiply u (having the dimension 1/time);
u = age in any units of time;
k = ratio of number of growth units to the (assumed) saturation number, with values between 0 and 1;

NOTE.—Published in February, 1941, *Proceedings*.

[1] Cons. Engr., Baltimore, Md.

v, y, y' = number of growth units, measured to different base lines, as described below;

b = number of growth units at saturation; that is, at the time of maximum growth, which is (mathematically speaking) at infinite time;

$\log_e c$ = time distance between two origins, as described subsequently;

a = number of growth units (from a previous life) at inception of the growth function that is now operating.

If the origin is chosen at that year in which the number of growth units equals one half of the number at saturation, the result is a symmetrical S-shaped curve

$$f\,u = \log_e \left(\frac{k}{1-k}\right) \qquad (1)$$

The abscissa, u, is measured plus from this origin with increasing years; ordinates, v, measured from the origin, are plus when u is plus, and ordinates, y', measured from a base line, are always plus; the factor, k, is the ratio of y' to the total number, b, at saturation. To another origin, at distance $\log_e c$ to the left of this midpoint origin the equation is

$$f\,x = \log_e c \left(\frac{k}{1-k}\right) = \log_e c + \log_e \left(\frac{k}{1-k}\right) \qquad (2)$$

The ordinate $y' = v + \frac{b}{2}$. If the curve begins tangent to a base line that is above the zero line by the distance, a, such that $y' = y - a$, Eq. 2 may be written

$$y = a + \frac{b}{1 + c\,e^{-fx}} \qquad (3a)$$

but in all that follows a equals zero, and $c = 1$; that is,

$$\frac{y'}{b} = k = \frac{1}{1 + e^{-fu}} \qquad (3b)$$

To use such a formula it is necesssry to know the saturation number, b, which of course it is impossible to know until all growth has ceased. However, if a smoothed curve through plotted data indicates a reversal of curvature, it may tentatively be assumed that the point of contraflexure is the aforementioned first origin; that is, $\frac{b}{2}$ above the base line. At the midheight point the slope of the tangent $\left(\text{that is, } \frac{dk}{dx}\right)$ is maximum, and is $\frac{1}{4}f$. In general, the slope is equal to $f\,k\,(1 - k)$, and therefore varies as a parabola referred to k. The annual increment, when $f = 0.3$, is $\frac{k_n\,(1 - k_n)}{k_n + 2.86}$, and the annual growth ratio is $\frac{k_{n+1}}{k_n} = \frac{1}{0.26\,k_n + 0.74}$, and therefore declines every year.

In Fig. 1 such a curve is shown, marked a, as well as others to be described. The vertical scale represents k; the horizontal scale represents $f\,u$ to the arbi-

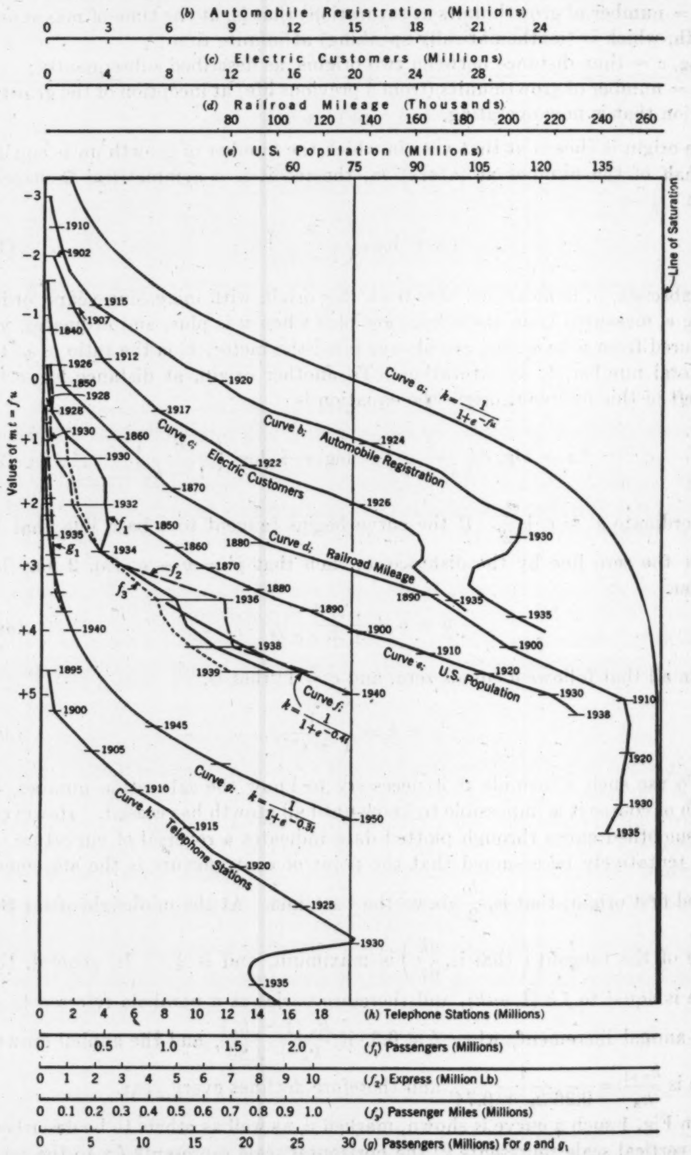

FIG. 1.—GROWTH INDICATORS (t EQUALS TIME IN YEARS, AND m IS A NUMERICAL FACTOR OF THE SAME TYPE AS f)

trary values noted at the bottom. The other curves represent the growth of various indicators, with abscissas as marked on each curve. The first of these (curve *b*) shows automobile registration in the United States, based on the year 1924 as the midheight point. Curve *c* (which is foreign to a discussion of transportation except in so far as it deals with distribution) represents the number of electrical customers, based upon the year 1926. Curve *d*, which probably is a complete one, represents the railroad mileage of the United States, based upon the year 1885. Already this curve has declined from its saturation point. The next curve, *e*, is the population of the United States.

To the right of these curves are three broken lines that represent, respectively, the annual number of airplane passengers, the number of passenger miles flown, and the pounds of air express, to include 1940. Through these curves is drawn an S-curve as a frame upon which to extend the data, the saturation number being assumed at about three times the present count. Beside it is a similar S-curve (curve *g*) upon which is redrawn, to much smaller scale, the number-of-passengers curve, g_1.

The horizontal scale for each of these curves is indicated by the years marked on them. The first curve (curve *f*) is merely indicative of the slope, because the data are so irregular as to permit almost any curve to be drawn through them, the irregular effects of the business depression being clear. The second curve (curve *g*) is based upon a saturation number of passengers equal to 12% of the total number of passengers (through and commutation) on the steam railroads of the United States in 1939.

The total future growth of air travel and air use is any one's guess. The data accumulated are clearly a poor indicator. If comparison is made first with the rate of growth of railroad mileage, then the engineer may count upon a continually increasing rate of growth for about fifty years, or say thirty-five years longer, before the midheight point is reached; but this comparison seems unfair, because in a little more than ten years the airline network has grown to a mileage that is comparable with one hundred years of growth of railroad mileage.

Seemingly, on the other hand, automobile registration is a good indicator, although it must be recognized that here the student is dealing with the private conveyance largely, whereas the commercial use of airplanes relates to common carriers. However, the automobile developed mostly during the short space of about fifteen years, and after the major expansion of the country had taken place (therefore at a time of slower growth in population, although, of course, some growth in registration has come from increased population). If the automobile indicator is used, one must assume, tentatively, that the period of half-growth will be approximately fifteen years, instead of fifty years.

The first airplane curve (curve *f*) is based upon a half-growth period of about fifteen years, and would yield as saturation values: 4,800,000 passengers, 24,000,000 lb of express, and 1,600,000 passenger miles. The equation (for the number of passengers) is

$$y' = \frac{4,800,000}{1 + e^{-0.4t}} \qquad (4)$$

in which *t* is the time in years from 1940.

The second curve (curve g) is based upon a half-growth of about twenty-five years, and a saturation number of 12% of the railroad passengers—that is, 60,000,000 passengers. The equations for express and passenger miles would be related. For this curve the abscissas and ordinates have been altered, as shown, the ordinates being one twelfth, and the abscissas four fifths.

These curves (curves f and g, Fig. 1) cover a wide range. The one reflects individual desire for transportation to a great extent; and the other is based upon common carrier transportation, which is influenced by a long period of growth in population, and a paucity of population in the early years. Because of the irregularity of the data it is impossible to fit any curve that is not open to serious objection, but since some crude basis of prediction is needed, the writer offers curve g for discussion, as being more likely of attainment. If it be correct there will be a half-growth period of about twenty-five years. In further discussion, therefore, this latter curve is used. Its equation is

$$k = \frac{1}{1 + e^{-0.3t}} \qquad (5)$$

in which t is the time in years, measured from 1950. The assumed saturation value for passengers is 60,000,000 per yr; and, for express, 180,000,000 lb per yr. From this curve, the growths in Table 1(b) are derived.

TABLE 1.—Growth Studies Applying to Air Transportation

(a) Annual Traffic at Newark, N. J.[a]				(b) Future Growth in the United States (Eq. 5)				
Year	Passenger fares	Freight, in Lb		Year	Value of k	Ratio[b] $\frac{k_{n+1}}{k_n}$	No. of passengers	Express, in lb
		Mail	Express					
1929	4,000	322,000	0	1939	0.0355	1.34	2,130,000	6,390,000
1930	30,000	905,000	47,000	1940	0.0475	1.33	2,860,000	8,580,000
1931	90,000	2,061,000	64,000	1941	0.0630	1.32	3,780,000	11,340,000
1932	91,000	1,730,000	213,000	1942	0.0840	1.31	5,040,000	15,120,000
1933	117,000	1,603,000	457,000	1943	0.1090	1.30	6,540,000	19,620,000

....	......	....	....	1949	0.4255	1.18	25,530,000	76,590,000
....	......	....	....	1950	0.5000	1.15	30,000,000	90,000,000

[a] Prior to opening La Guardia Field. [b] Where $\frac{k_{n+1}}{k_n} = \frac{1}{k_n(1 - e^{-f}) + e^{-f}} = \frac{1}{0.26\,k_n + 0.74}$, for $f = 0.3$. k_{n+1} = value of k for the $(n + 1)$th year, etc. For $f = 0.3$ this ratio gives 35% annual growth at the start, and 0% at the end of the life, and for $f = 0.4$, 50% and 0% respectively.

The Individual Airport.—The foregoing values apply to the United States as a whole. There are no means for predicting the volume of traffic for each individual airport, because competition between nearby airports, local business conditions, etc., make a prediction far more hazardous. For the sake of discussion, however, the writer will apply the 1950 ratio—14 : 1—to individual airports, meaning that by the end of a period of eleven years the volume of traffic will be fourteen times as great as in 1939. After five years Baltimore (Md.) exceeds such a curve by about 15%.

As indicative of such growth the traffic per annum at Newark, N. J., is given in Table 1(*a*). Transfer of the airlines to La Guardia Field caused an abrupt drop after 1938.

Density of Traffic

There is little experience to guide a designer in determining how many planes can be landed and discharged from an airport.[2] Such experience as there is points to a minimum time between take-offs of about 2½ min. This would indicate a rate of 24 planes per hr, if systematically scheduled. Probably if double-width runways are provided this time can be reduced materially —perhaps by one half; but this is questionable.

If transport planes in the next ten years average 20 passengers each, landing or taking off from terminal airports, one may consider the probable passenger load to be roughly 500 per rush hr. For intermediate airports one can assume a capacity of fourteen times the values for 1939 as being the growth up to about the year 1950.

Size of Airplanes

There is no basis for predicting the growth in the size of aircraft that is not subject to much criticism. The growth curve may quite likely be an **S**-curve such as has been analyzed already; but the constants which determine the curve are indeterminate for want of basic data. Perhaps one may draw some conclusions from the rate of growth in speed, as indicated by the Schneider Cup Races, but it should be noted that in many cases the winner was a seaplane. For all winning planes, whether land or seaplanes, the horsepower increased roughly along a biometric curve. Similarly the top speed, when plotted, approximates such a curve and shows clearly the flattening off of the curve as it approaches what (in the light of present knowledge of the compressibility of air) is probably the maximum speed attainable in flight.

Airplane dimensions are more difficult to plot because they depend so largely upon the individual ideas of the designers of the differing types manufactured. It is probable that the rate of growth in size of land planes is approaching a maximum, but it is also probable that seaplanes will continue to grow beyond the limits of the land planes. The restriction imposed by the size of available landing areas is already affecting the first class, whereas there are areas along the ocean coasts and the Great Lakes in which it is possible to take off and land a large seaplane within reasonable access to important business centers.

In 1936 the writer made the prediction for seaplanes given in Table 2. The Pan American Clipper ships operating across the North Atlantic, for instance, have the actual dimensions listed under 1939. However, airline operators consider these estimates to be too conservative.

One American seaplane manufacturer has constructed his factory with a 300-ft clear span, and 40-ft clear height, anticipating the need for this added space in the not distant future. A proposed German design has a wing span of

---

[2] Some pertinent information will be found in "Forschungsvergebnisse des verkerswissenschaftlichen Instituts für Luftfahrt an der Technischen Hochschule Stuttgart," by Carl Pirath, Verlag von R. Oldenbourg, Berlin, 1930.

289 ft, a carrying capacity of 170 passengers and crew, length 158 ft, gross weight 250,000 lb. Mr. I. Sikorsky[3] has stated his belief in a ship of 1,000,000-lb gross weight as an engineering possibility. Such a plane might have a wing span of 450 ft. An English writer envisages a 500-passenger seaplane of 400-ft wing span, which will cross the North Atlantic in 12 hr.

TABLE 2.—PREDICTED GROWTH IN SEAPLANES

Year	Span of wings, in ft	Over-all length, in ft	Height, in ft	Gross weight, in lb	Weight per sq ft, in lb	Tail span, in ft	Passengers (sleeping)
1935	130	90	25	52,000	23.5	40	....
1939[a]	152	106	27.57	82,500	28.7	45.77	40
1945	175	110	32	100,000	31	42	50
1950	200	130	34	140,000	35	43	75
1955	250	160	37	250,000	40	45	100

[a] Actual values for Pan American Clipper ships.

SIZE OF AIRPORTS

Mathematical Analysis.—In this paper attention is centered on landing fields for landplanes. The size of an airport depends, first, upon the obstructions in the vicinity. Until such obstructions are removed the landing area is reduced by some multiple of the height of the obstruction. In 1925 it was officially ruled that no area could be used for take-off or landing purposes whose distance from an obstruction was less than seven times the height of the obstruction. This rule was supplanted by a ratio of 10 : 1 very shortly; then by 15 : 1; and at present by 20 : 1; but the new (tentative) obstruction ratios are 30 : 1 on runways not to be used for instrument landings,[4] and 40 : 1 for those on which instrument landings are proposed. In this paper, therefore, it will be assumed that all such obstructions have been removed, and only the net dimensions will be considered available.

The length of a runway is determined primarily by two factors: (*a*) The take-off (or landing) run, while the plane is still on the ground or is just hovering; and (*b*) the length required for a path that will just clear an officially defined obstacle. In general, with brakes and wing flaps, the take-off run exceeds the landing run, and the latter need not be considered. The actual ground run is very much less than the total length of runway.

Although all pilots are required to warm up their engines and test them before taking off, there have been numerous cases in which the engines failed before any considerable height was attained, and cases in which the plane was so heavily loaded that it was unable to take off at all. In the single-engine plane the pilot must do the best that he can if the engine fails, and select a spot on which to land; in the multi-engine plane some power is still available to lengthen the landing glide, and therefore to multiply the chances for a safe re-landing. In any event, the pilot must choose between a straight glide, in the same direction as the take-off, or an attempt to turn in the hope of again regaining the airport. In the turn he may also suffer, or gain, from side slip, which in effect increases the gliding angle.

---

[3] *Journal of The Aeronautical Sciences*, December, 1936, Vol. 4, No. 2, p. 75.

[4] Airport Approach Standards (Tentative), *Civil Aeronautics Administration*, August 26, 1940

No one can predict at what time the engine, or engines, will fail; hence the following analysis is predicated upon determining the size of field required such that a pilot may re-land by effecting a turn (of 180° or less), regardless of the point at which failure occurs.[5] Side slip is assumed to be zero. The take-off angle, the glide angle, the speeds, and other factors in relation to size and power, are related to certain fundamental characteristics of airplanes. The relations are not identical for all makes of plane; and hence the resulting answer is more a generalized than a specific one.

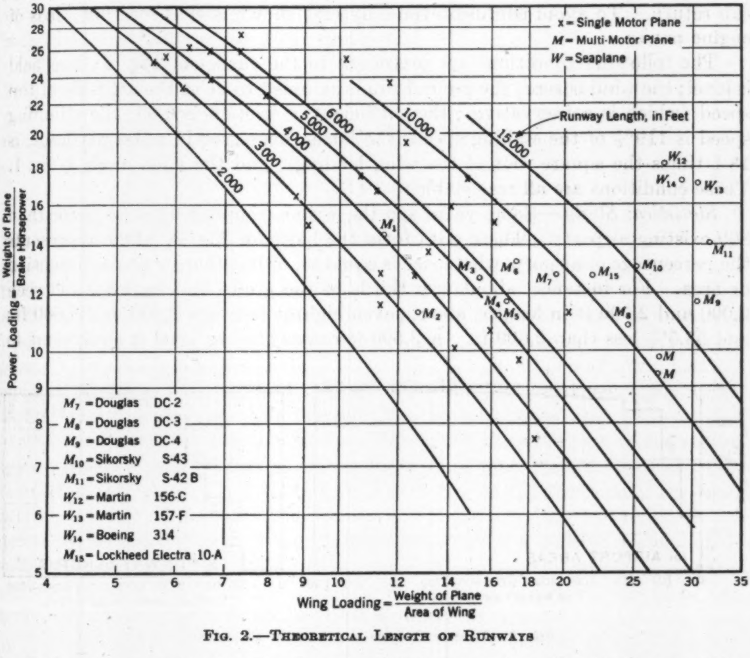

FIG. 2.—THEORETICAL LENGTH OF RUNWAYS

This answer appears in Fig. 2. The abscissas are the wing loading, and the ordinates the power loading. Wing loading is merely the weight of the plane per square foot of wing area; the power loading is the weight of the plane divided by the brake horsepower; both are factors that are known for various models, and are annually published in aviation magazines. In Fig. 2 the curves represent the length of runway on a square landing area within which a plane may re-land, with curving glide, based upon the two factors described. On this figure are also shown a number of present models, plotted according to their wing and power loadings. The points are classified as: Single engine planes, denoted by the letter, x; multi-engine planes, denoted by the letter, M; and seaplanes, denoted by the letter, W. Certain of these planes are identified by manufacturer's name and the model number; others can be identified by reference to published lists in aviation magazines.

---

[5] "On the Necessary Size of Aerodromes in Order that a Landing May Be Made if the Engine Fails When Getting Off," by H. Glavert, *British Reports & Memoranda No. 996*, January, 1926.

It will be noted, first, that for fields larger than 5,000 ft the spacing of the curves becomes very small, so that there is little gain by enlarging the field beyond 5,000 ft. A second point to be noted is that there is relatively little gain from a 4,000-ft field to a 5,000-ft one. It is also evident, third, that none of the multi-engined planes can return safely if all engines fail, but that with one half, two thirds, three quarters, or more of the engine power available, they can return. To avoid confusion the only case shown is that for 100% loss of engine power.

The following conditions are precedent to the curves of Fig. 2: The field is level; the wind is zero; the ground run is assumed to be at the attitude of top speed (which is conservative); the coefficient of friction is 0.05; the climbing speed is 119% of the stalling speed (the latter, expressed in miles per hour, is 18.1 times the square root of the wing loading); and the glide angle is 5 : 1. These conditions are all reasonable.

Statistical Study.—Some years ago the writer compiled data on more than 800 existing airports. These data form the basis for Fig. 3, which represents the percentage of airports whose size is equal to, or less than, a given dimension or area. For instance, about two thirds of the group had runways between 2,000 and 2,500 ft in length; about seven eighths between 2,500 and 3,000 ft; and 98.5% less than 5,000 ft. A 2,500-ft runway at sea level is equivalent to about 3,000 ft at El. 3,000. In Fig. 3, fields are included regardless of their elevation above sea level.

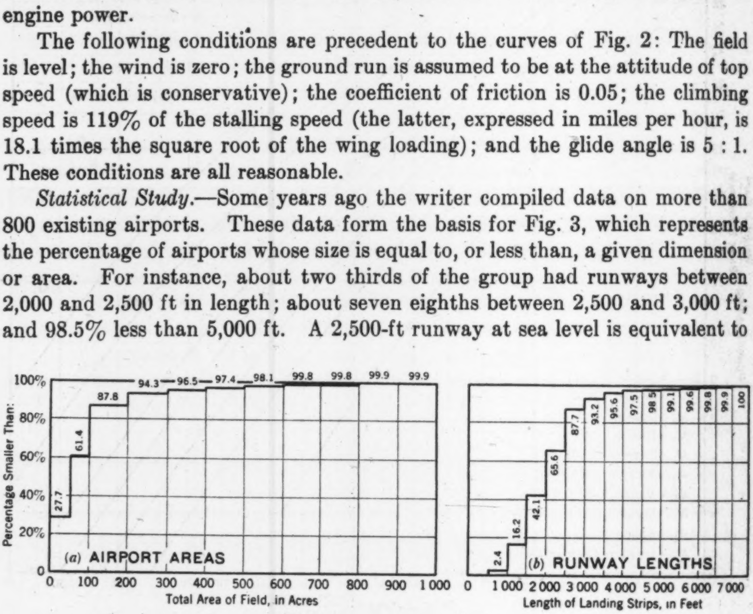

FIG. 3.—DESIGN CURVES FOR AIRPORT PLANNING

Probable Maximum Size.—In view of the large investment represented in airports it is scarcely likely that the size can be increased beyond 5,000 ft for even important ports, and it is certainly true that for many the size will not be enlarged beyond present dimensions because they cannot be enlarged.

In view of the utilization of multi-engined planes, the prevalence of wing flaps, and the possibility of other improvements, it seems that a fair conclusion to be drawn is that 5,000 ft probably will be the maximum size required in the future for airports intended for airplanes. Plane designers will be forced to design planes that can use fields of such size safely. For seaplanes, however, two to four miles is the size under consideration.

For lighter-than-air ships, fields on which a hangar is to be provided will also require approximately 5,000-ft dimensions. For a hangar 1,000 ft long, with a 2,000-ft approach at either end, 5,000 ft will be required on the axis of the hangar. If, now, the hangar is rotatable, a 5,000-ft diameter will suffice. If means are developed for handling a ship into, and out of, a fixed hangar regardless of the velocity of cross winds, then the field may be restricted to 5,000 ft on the hangar axis, and perhaps 3,000 ft at 90° to the axis. Of course on such a field other space is needed for auxiliary buildings and storage.

The combined conclusion, then, is that probably a 5,000-ft square field, free of obstructions, at sea level (or of larger size for high altitudes) will be the maximum size required for major airports.

Density of Traffic.—Such a field will handle traffic up to the limit of perhaps 24 planes per hr on a single-width runway. Should double-width runways prove to be successful in operation the capacity will be increased. When congestion becomes too great a new field must be developed.

FIELD ARRANGEMENT

The question of field arrangement largely falls outside of the purview of this paper. The size of the airport, however, is determined in part by the presence of buildings upon it. The buildings should be located with reference to the runways so as to allow not less than 1,400 ft of clear width, centered on each runway, and if space permits, this width should be increased to avoid the presence of disturbing eddies whose intermittent character can create a severe hazard to planes landing or taking off. Such eddies may persist for a distance equal to 10, 20, or more times the height of the building, and they slowly widen as they move away from their source. Nearby hills, trees, and other outside obstructions are also a source of such eddies, and if the eddies are of the rolling type, with their axis horizontal, as results, for instance, from a grove of trees, their effect is to cause a sudden and rapid deviation in the direction of the wind near the ground surface which may cause the plane to appear as though forced down, or suddenly lifted. A field located adjacent to a body of water is also subject to variations in the rate of ascent of the rising, heated air, giving the same effect as a rolling eddy. The size of the field, therefore, should be determined with such eddies, and vertical currents, in mind.[6]

AIRPORT FACILITIES

Administration.—The building that houses all means for serving the public will be called, for convenience, the "air station." Such a building will contain the airport administration, the airline ticket and accounting offices, the personnel for flight control, the personnel for meteorological service, the postal, express and such services, and finally (where required), customs, public health, and immigration services. Each of these will be considered in the light of present knowledge.

---

[6] "Wind Velocity in Relation to Height Above Ground," by W. Watters Pagon, *Engineering News-Record*, May 23, 1935.

The airport administration offices will probably be restricted to a space not greatly exceeding present requirements. Each airline will require not less than 12 ft of counter length and 200 sq ft of space behind it for the sale of tickets. If the airport is an intermediate one, an additional 600 sq ft of space will be required for accounting work, for teletypewriters, etc. If it is a terminal port, and, of course, if the main offices of the airline are at such a terminal airport, a large area may be required, or even an entirely separate building.

The size of the airport control room is a debatable matter. Opinions range from 144 sq ft to 256 sq ft, or more. An additional space, about equal in size, is needed for housing the equipment and accessories that need not be within the control room itself.

The space required for airway flight control and for meteorology increases from year to year. Only in recent years has there been need for control of traffic on the airways, but each year there will be increasing density of traffic, and increasing space in the station will be required for control. At present there is evidence that about 5,000 sq ft should be available, on one floor, close below the control room, for these facilities. In addition, "meteo" will require outside space, on the ground or on the roof, for instrument shelters. In Europe air police must also be accommodated.

The space required for postal and express services is dependent largely upon the type of operation as well as upon the volume of traffic. Where truck deliveries can be made, profitably, directly to and from a plane, little or no space is required in the station. With increasing volume the necessity will arise for inter-transit storage of express (between planes, or between planes and trucks); and in course of time the postal authorities will probably begin to demand space. These areas are completely indeterminate. The writer has attempted to obtain some clue from the express companies as to their requirements, but without success. Hence, the designer of an air station must rely entirely upon his imagination, and—having done so—should locate postal and express space so as to permit of a great expansion.

The space required for customs, immigration, and public health services will be considered only where there is likelihood of international airplane traffic. The writer has provided an area of 1,350 sq ft for these combined services at the Transatlantic Seaplane Base of the Baltimore (Md.) Municipal Airport[7] which, for the present, at least, has been satisfactory. The counter for customs inspection occupies 60 ft. When seaplanes that will carry more than 100 passengers are introduced, no doubt there will be need for additional space.

The spaces that occupy the greater part of the air station are those that serve the public generally, rather than the air traveler. Just as in the early days of the railroad, the general public has an intense interest in watching the operations of an airport. On Sundays and week ends, on holidays, on race days or days of exhibition flying or when some distinguished visitor may be seen, extraordinary crowds mill about the airport and into the station. Space for shelter, sanitary facilities, restaurants, etc., must be provided within reasonable limits.

---

[7] *Proceedings*, Am. Soc. C. E., October, 1940, p. 1488.

At present no one knows what are reasonable limits. During the week there are almost no visitors—only the traveling public; on week ends come the crowds. Table 3 gives some estimates of the number of persons who visit airports in different cities of the United States. In Continental Europe and in England the number is comparable and even larger. Many of the estimates are pure guesses, but they are still indicative.

TABLE 3.—THE NUMBER OF PERSONS VISITING AIRPORTS[a]

City[b]	An ordinary summer day	A summer week end	Largest recorded in one day
Akron, Ohio	1,500[c]	....	45,000
Washington, D. C. (Hoover)	500 to 600	1,000 to 1,200	1,500 to 2,000
Atlanta, Ga.	500	6,000[c]	50,000
Boston, Mass.	500 to 1,000	....	10,000
Buffalo, N. Y.	400 to 500	15,000[c]	75,000
Camden, N. J.	500	2,000 to 5,000	25,000
Chicago, Ill.	100	1,000[c]	200,000
Cincinnati, Ohio	200	5,000[c]	35,000
Cleveland, Ohio	3,000 to 4,000	28,000[c]	140,000
Columbus, Ohio	2,000 to 5,000	10,000 to 15,000	50,000
Dallas, Tex. (Love Field)	1,500 to 2,500	15,000 to 25,000	80,000
Dayton, Ohio	300	5,000	15,000

[a] "Airports," by Henry V. Hubbard, Miller McClintock, and Frank B. Williams, Harvard Univ. Press, 1930. [b] Special name of airport in parentheses. [c] Sunday only. [d] Estimate made on basis of 3 persons per automobile.

In his search for an indicator of the required extent of these public facilities the writer turned to railroad experience. Some years ago the American Railway Engineering Association collated information as to railroad stations throughout the United States, and derived diagrams[8] based upon the number of "rush-hour passengers." Of course, the rush hour is congested largely by commuters, for whom the station serves mostly as a gateway from train to street, and for whom little waiting space and few sanitary or restaurant facilities are required. Of course, also, the railroad station must be of a size to accommodate crowds assembled to greet friends or notable persons, without undue congestion.

It is probable that for ten years to come the crowds at an airport will far exceed those at a railroad station, in relation to the number of passengers; it is certain that for ten years to come there will be little business of commuting by airplane. As a result, the indicators described herein are all dependent upon a crude estimate, or even guess, as to the basic factor underlying them all;

---

[8] *Bulletin*, A.R.E.A., Vols. 24, 25, 26, 1923–1925.

but they possess this important characteristic: They are all consistent among themselves. If, then, the assumed basic factor proves to be correct, the station will be consistent in design; and in order to allow for error, the basic assumption should be underestimated. Then the design can be fortified by such planning that the facilities may be enlarged pro rata as the need arises.

From the railroad data the writer derived formulas for each of the public services. All depend upon the estimated number of rush-hour passengers (designated as p); some being in linear relation, others as the square root. Each curve may have a fixed, or initial, value as follows:

Concourse, in square feet	4,000 +	$4.4\,p$
Terrace, or outside area, in square feet		$300\sqrt{p}$
Men's smoking room, in square feet	500 +	$0.3\,p$
Women's rest room, in square feet	500 +	$0.6\,p$
Total inside seats, number		$17\sqrt{p}$
Men's toilets, in square feet	500 +	$0.5\,p$
Water closets, number		$0.55\sqrt{p}$
Urinals, number		$0.35\sqrt{p}$
Lavatories, number	4 +	$0.0044\,p$
Women's toilets, in square feet	400 +	$0.33\,p$
Water closets, number		$0.40\sqrt{p}$
Lavatories, number	6 +	$0.004\,p$
Telephone booths, number	1 +	$0.006\,p$
Telegraph office, in square feet	60 +	$3.5\sqrt{p}$
Dining room and restaurant, in square feet	500 +	$2\,p$
Seats, number	15 +	$0.08\,p$
Kitchen, in square feet	200 +	$1.2\,p$
News stands, in square feet		$11.5\sqrt{p}$

On the Continent it is customary to provide hotel facilities for the traveler, but this is not usual in the United States. However, some space should be provided, with appropriate toilet facilities, for visiting pilots, male and female, and there should be sleeping quarters for airport operating and for "meteo" personnel, these being dependent entirely upon the local conditions at the airport. If there are already such accommodations of suitable quality in the near vicinity they may be omitted, of course, except perhaps for operating and "meteo" personnel.

As time goes by an urgent need will be found for garaging automobiles of the traveling public, and such a garage should provide moderate accommodations for the airport personnel. In addition, large open areas should be set aside for parking the cars of the visiting public, with adequate roadways designed to avoid the congestion on visiting days.

HANGARS

The area and size of hangars are problems that are peculiar to each airport. For intermediate airports only one such area is needed, with hangar storage space as required for the local planes that base there. For terminal airports there must be hangars of number and dimensions suited to the requirements of the airlines basing there, in addition to the small local planes.

For important intermediate and terminal fields there is probably need for hangar area of 50,000 to 75,000 sq ft; for smaller airports, proportionately less. In one hangar space should be provided for repair shops and storage areas, and the writer suggests areas (in square feet) approximately as follows:

Engine overhaul shop	3,600
Engine storage	1,200
Wood shop	1,500
Paint shop	1,200
Metal shop	2,000
Propeller shop	800
Fabric shop	900
Machine shop	700
Forge shop and heating plant	1,000
Radio shop	500
Instrument shop	500
Parts storage	4,700
Accessory shop	300
Shop offices	1,000
Toilets, locker room, etc	2,000
Field equipment storage	3,000
	24,900

The ceiling height of the hangar should be from 30 to 35 ft, and of the shops preferably 18 to 20 ft. If the shops are situated within the hangar the offices, locker and toilet rooms, etc., may be placed in a second story. Some of the first-story shops may require additional height, and should be placed so as to utilize a part of the second story area.

FUELING

It is unnecessary to attempt a formula for the capacity of the fueling system. If servicing can be secured readily from nearby sources, it may be entirely proper to fuel directly from tank trucks; otherwise there should be underground storage of sufficient volume, and pumps of sufficient capacity, to minimize or to avoid delays in fueling. The problem is local to each airport.

SUMMARY

In setting down the statistical and approximately mathematical data of this paper the writer (to use a slang expression) is "putting his neck out." Some of the predictions are based upon reasonable factual assumptions, some upon comparison with railroad and other experience, and some upon airport experience and the judgment that derives from such experience. Predictions of growth are naturally very hazardous, because the growth of the air transportation industry has not yet progressed far enough for the determination of the trends; but, of even more importance, predictions are difficult because the irregularity of the data (resulting from the effect of the business depression) is such as to prevent the fitting of any accurate growth curve. Such curves have much value, however, in that they have been found to express growth relationships for other variables with considerable success; but they always must be projected with due caution, because it is noteworthy that sudden changes in conditions postulate the ending of the previous growth curve, and the inception of a new one. This is illustrated well in the curve, *h*, of Fig. 1, showing the number of telephone stations in the United States, in which there first appears a change of the curve during the World War, and then the slump due to the depression. It is highly unsafe, therefore, to project any such curves more than ten years in advance, and the result even at the end of ten years may be seriously in error.

The writer offers the data, and the deductions therefrom, for the sole purpose of inviting constructive criticism in order that, by concerted action, the industry may derive some idea, even though approximate, of the rate of growth, and the resulting requirements that airports must meet in the near future. He expressly omits a discussion of the engineering features of design because so much has already been written on the subject, much of it now obsolete, to be sure.

It is hoped, therefore, that the profession will criticize, freely, all the statements made, and in so doing will supplement the data and the deductions to the same end that the writer has in mind.

DISCUSSION

William E. Rudolph,[9] **M. Am. Soc. C. E.** (by letter).—Mr. Pagon has presented most interesting data for determining the rate of growth of air travel and resulting requirements that airports must meet in the future. However, the writer would invite attention to another important factor that is certain to influence the rate of increase of air travel, although not inherently part of airport design—that of speed and comfort of travel between airport and business center.

At present the traveler between Chicago, Ill., and St. Louis, Mo., or between New York, N. Y., and Philadelphia, Pa., actually spends as much time in motor buses to and from airports as he does aboard the plane. Necessarily, these airports are at considerable distances from business centers, with long and not too comfortable trips through crowded city traffic lanes the unavoidable consequence. Whereas air traffic conditions entering and leaving airports may be improved by building longer and wider runways as discussed in Mr. Pagon's paper, surface traffic conditions in crowded city streets will require special and far more expensive remedies. The business center of the future cannot move to the airport as it once encircled the railroad stations of the past—because business requires high buildings, which are not desirable near airports. Hence, there is the obstacle of distance to be surmounted at airports, and the best solution of this problem may be in trunk line motor travel arteries to adjacent business centers, a major construction feat.

The rapid growth of air travel would appear to be predicated upon two major advantages over other methods of transportation—time saving and greater comfort.

From the standpoint of time saving, the future will determine where the line should be drawn between those trips that may better be made by airplane, and those falling within the zone of the railroad and motor vehicle. As the distance that may be advantageously traveled by air becomes shorter and shorter, so will the volume of air travel increase by leaps and bounds, because there are far more passenger trips and passenger miles in short journeys than in long journeys. Here the factor of lost time at air terminals looms up as important, inasmuch as its proportion of the total travel time is considerably larger for short trips than for long trips.

From the standpoint of greater comfort, air travelers whom the writer has met agree almost without exception that the airplane is far more comfortable than the railroad or motor car. The one refreshes, the other fatigues. The writer encourages his staff men to use the airways because he considers this to make for higher efficiency; if a man's work is of sufficient value to his employer to justify his time and expenses in travel, it is equally important that this employee be at his best for performing such work upon arrival at his destination. Again, people of the present day are not content with the travel conditions to which their parents were accustomed, and the next generation will look askance at that which is considered comfortable today—another reason why air traffic should grow.

---

[9] With Anaconda Copper Mining Co., New York, N. Y.

Particularly in mountainous regions does the differential on time saving, and decreased "wear and tear" upon the individual, become apparent. Here the railroad must adopt a circuitous route, whereas the plane flies directly over Nature's obstacles. The railroad pays endless toll in fuel and in carrying charges upon large capital investment in such sections, which places the airplane at a decided advantage. Thus a greater rate of increase might be expected in airplane passenger travel in mountainous regions of dense population than in flat regions where railroad locations and motor roads follow direct courses. In the development of South America, which would seem to be the principal task of the future, air travel should play an important part, in view of that continent's rugged terrain.

Donald M. Baker,[10] M. Am. Soc. C. E. (by letter).—The use of the type of curve suggested by the author in forecasting future air traffic is based upon a sound theoretical premise, since such traffic will increase in magnitude with population. This soundness is further borne out by examples of the growth of other activities and their similarity in growth pattern to the theoretical curve given in Fig. 1.

Uncertainties as to the probable location of the point of inflection on the air-traffic curve, and consequently of the probable saturation point, can be expected with the relatively small amount of basic data yet available, but the reasoning followed, coupled with the fact that the author calls attention to the danger of attempting to forecast for a period longer than ten years, is sound, and allows a proper safety factor to be used when results of the forecast are used. The formulas presented for computing areas necessary for various facilities are of much value.

The reasoning and supporting data from which the conclusion is reached that a runway 5,000 ft long represents the probable maximum that will ever be required carry conviction, and should be welcomed by those responsible for acquiring and planning airports. Heretofore lengths of runways have shown a constant increase, and no sooner had a port been constructed according to the latest standards than such standards were raised, and inadequacy resulted. From the present time forward the length of runway will control the plane designers, instead of the latter controlling the length of runway. The extremely large proportion of airports with runways much shorter than 5,000 ft is undoubtedly due to the fact that most of the land for airports now in existence was acquired in the late 1920's or early 1930's, when U. S. Department of Commerce ratings for a Class 1 airport stipulated two runways at least 2,500 ft long, at an angle greater than 60°; and for a Class 2 airport one runway 2,500 ft long, in the direction of the prevailing wind, or two runways 2,000 ft long, at an angle greater than 60°. Instrument flying or landing was then practically unknown, and freedom from fog was a very important factor. Planes flew at elevations of from 5,000 to 6,000 ft, landed or took off at an angle of 1 in 7. Two or three transport landings a day were big business.

---

[10] Cons. Engr., Los Angeles, Calif.

Any flat open area of about 160 acres, even if surrounded by residential development, was suitable for an airport (the term "transport terminal" was unknown), and the owner of such a property, provided he had suitable political connections and did not ask an exorbitant price for his land, was usually able to dispose of it for use as the local airport. Possibilities of future expansion were given little thought.

With present stratosphere flying, instrument landings, greater speed, weight, and size of ships, obstruction ratios increased to 1 in 40, and with reasonably definite information as to ultimate maximum size of fields required, it is possible to consider intelligently the question of the adequacy of existing fields, and to plan for ultimate extensions in the length of runways and the size of fields.

The data given by the author indicate that, in the near future, many fields will have to be increased in size. Additional adjacent land will have to be acquired, or the existing sites abandoned and new and larger sites purchased. When faced by this situation, the agency owning and operating the site must consider the economics of the situation.

Only large metropolitan centers require that the site to be used as a transport terminal have 5,000-ft runways; but, although open unimproved areas of 160 acres (which will accommodate 2,500-ft runways) occur with reasonable frequency at fairly close-in locations in such areas, 640-acre tracts of this character are scarce.

The major factor in encouraging air travel is the time saved in comparison to other methods of travel, usually rail travel. Already fares for air travel have been reduced to a point that, between termini farther apart than overnight trips by rail, a saving can be shown over rail travel if but a nominal value is placed upon the traveler's time.

In rail travel the time spent between the points of origin and destination and the railroad depot is a negligible factor, both because such depots are usually located close to the business district, and also because such travel time is an extremely small proportion of the total time spent on a rail trip. Time spent in ground travel between points of origin and destination and the airport is a much more important factor, particularly when the trip is relatively short. In 1928 the writer presented a paper before the City Planning Division of the Society,[11] the conclusion of which was that there was little time saving in air over rail travel in distances of much less than 500 miles, when considerable time was required for ground travel at the beginning and end of the trip. This was based upon scheduled air and rail speeds of 100 and 33.3 miles per hr, respectively. It was borne out by the fact that there was then very little "short-haul" passenger traffic.

At present these speeds have increased to approximately 250 and 55 miles per hour, respectively, and "short-haul" passenger traffic has increased materially. When a one-way air trip of 500 miles involved a total time between points of origin and destination of from 6 to 6½ hr, usually with daytime flying, at least two (and sometimes three) working days were spent away from the place of business, whereas overnight rail trips allowed a complete working day at the destination with but one day away from the traveler's place of business. Present-day speeds of 250 miles per hr by air allow a person nearly as much time at his destination, and he can sleep at home. This has greatly increased the "short-haul" traffic.

[11] "Factors Governing the Location of Airports," by Donald M. Baker, *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 269.

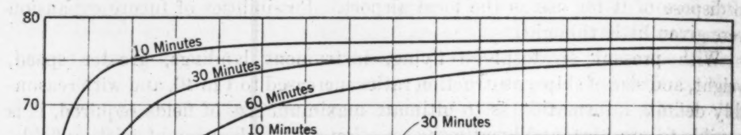

FIG. 4.—TIME SAVED BY AIR OVER RAIL TRAVEL

Fig. 4 shows the saving in time of air travel over rail travel, based upon air and rail speeds of 100 and 250 miles per hr, and 33.3 and 55 miles per hr, respectively, with varying times of ground travel to and from the airport. Present higher speeds in air travel increase the percentage of time saved from 10% to 12% over former speeds, but likewise show a greater effect in time of ground travel.

With air speeds of 100 miles per hr, percentage of time saved in air over rail travel increases 9% with a decrease in time distance of from 60 min to 10 min in one-way ground travel for 500-mile trips, and 17% when air speeds are increased to 250 miles per hr. For 1,000-mile trips, the time saved is 5% at 100 miles per hr, and 9% at 250 miles per hr as compared with comparable time periods of ground travel.

Cost of land in metropolitan centers varies inversely with the distance from the business center. Improved land will cost from 4 to 10 times more than unimproved acreage will cost in the same location. If the size of an existing airport must be increased, and such increase is prohibitive in cost because of the price of additional land, the question of acquiring a cheaper outlying site will depend upon the additional cost of maintaining reasonably similar time of ground travel; and this in turn involves a problem of determining the future magnitude of traffic to and from the airport and the business district or higher class residential district, unless the new site can be located near an existing high-speed rail line or highway.

Data given by the author indicate a volume of air traffic in 1940 amounting to 2.2% of the national population, and an estimated volume in 1950 amounting to about 22% of the then estimated population, or a per capita increase of 10 times. Based upon population of metropolitan centers, these percentages will be much greater. The air traffic at the principal Los Angeles air terminal for 1940 was 210,000 passengers, an increase of 80% over that for 1939, and represented between 7% and 8% of the metropolitan population. If such traffic were to increase in accordance with the rate estimated by the author for the nation, air traffic in Los Angeles would be of the order of 2½ millions in 1950. Such traffic would, without question, justify considerable expenditures for improving the accessibility of any major air terminal, these expenditures being in excess of savings made through acquisition of outlying land at a price lower than that for land closer in.

The writer believes that, in the past, inadequate consideration has been given to the economics of the location of airports, but feels that with increasing information and basic data becoming available, such as that contained in the paper, there should be no excuse for such lack of consideration in the future.

W. Watters Pagon,[13] M. Am. Soc. C. E. (by letter).—Mr. Rudolph stresses the relation of ground time to air time for short hops between near-by cities. Mr. Baker deals mathematically with the same subject, by the reconstruction of his former figure to bring it into harmony with modern air speeds. The writer suggests that such discussions should emphasize that it is the difference in ground time to the air terminal as against the rail terminal, rather than the actual time. For example, the writer can reach the Baltimore (Md.) Municipal Airport in 15 to 18 min from his office, as opposed to 10 min or more to either of the rail terminals, and this ratio applies to almost all of the Baltimore business district. For the short hop from Baltimore to Philadelphia, Pa. (about 96 rail miles), the ground time in the two cities is 50 to 55 min to the air terminals as opposed to 25 to 30 min to the rail terminals; and the traveling times are slightly more than 0.5 hr and 1.5 hr, respectively, with an approximate saving of half an hour.

The City of Los Angeles, Calif., has studied the problem of providing air taxi service from one or more central airports to scattered "satellite" airports of small size. Small airplanes or autogyros will undoubtedly be used in the future to minimize the ground time to remote airports.

Mr. Rudolph's comments on the relative comfort of the airplane in mountainous regions are worthy of inclusion in the prediction of the growth of air travel. The writer is indebted to both discussers for their comments.

When a growth prediction has been made, from time to time it is desirable to check the actual progress against the prediction, to detect any changes of trend. This is especially true in the present matter because of the erratic growth curve from which the writer's curve has been projected. Table 4 brings the trends up to July, 1941, and for convenience the results for seven months in 1941 have been amplified in the same ratio that prevailed in 1940 to obtain the figures for 1941. The number of passengers is slightly in excess of the prediction; the pounds-of-express curve has been much accelerated for eighteen months by war conditions. The data are taken from the "Survey of Current Business."[13]

METHOD OF PREDICTING THE RUNOFF FROM RAINFALL

BY RAY K. LINSLEY, JR.,[1] AND WILLIAM C. ACKERMANN,[2]
JUNIORS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. BERTRAM S. BARNES, RICHARD VAN VLIET, LEROY K. SHERMAN, FRANKLIN F. SNYDER, AND RAY K. LINSLEY, JR., AND WILLIAM C. ACKERMANN.

SYNOPSIS

The problem of estimating runoff accurately and quickly from reported rainfall is the most difficult phase of river forecasting. The writers have analyzed hydrological and meteorological records of the Valley River Basin in North Carolina to develop a rational method of predicting runoff based on average rainfall and evaporation from a standard land pan.

DESCRIPTION OF THE BASIN

The Valley River above the U. S. Geological Survey gaging station at Tomotla, N. C., drains an elliptical basin of 104 sq miles. Tomotla is near the lower end of the river, which follows roughly the long axis of the ellipse. Topographically the basin consists of a gently rolling valley floor bounded on the north by the Snowbird Mountains and on the south by the Valley River Mountains. Elevations within the basin range from 1,600 to 1,900 ft above sea level on the valley floor and from 3,000 to 4,500 ft above sea level along the surrounding rim. The channel slopes of the river average about 30 ft per mile in the upper half of its course and about 15 ft per mile in the lower reaches.

The rock underlying the Valley River Basin is metamorphic, consisting mainly of gneisses and mica schists. The structure is rather complicated as the rocks are extensively faulted. A thin belt of marble underlies almost the entire basin. There is an extensive local alluvial fill from 20 to 30 ft deep over part of the basin that results in sustained ground-water flows. There is no evidence of loss of water from the Valley Basin by deep seepage.

NOTE.—Published in June, 1941, *Proceedings*.

[1] Asst. Hydrologic Engr., U. S. Weather Bureau, Sacramento, Calif.; formerly Junior Hydr. Engr., TVA, Knoxville, Tenn.

[2] Asst. Hydr. Engr., TVA, Knoxville, Tenn.

The City of Andrews with a population of about 2,000 is located near the center of the basin. The remainder of the area is rather sparsely settled. The valley floor, comprising about 60% of the total area, is dominantly cleared and about one half of this is in cultivation. The remaining area is forested, with mixed hardwoods and long-leaf pine at intermediate levels and hardwoods at the higher elevations.

DATA USED

Since appreciably different runoff characteristics exist in the various seasons of the year, it is essential to segregate data by seasons before attempting an analysis. In this study only the flood season, which begins about the middle of December and extends to the middle of April, is considered. This period falls within the dormant season and coincides with the period of general cyclonic rains. The limits of this season for a particular year can be determined by inspection of the temperature and stream-flow records. The study is based on the three flood seasons of 1934–1935 to 1936–1937.

Average rainfall was computed by the weighted-area method, using the records at Andrews, Hyatt Creek, Tatham Gap, and Old Road Gap in North Carolina. Time of rainfall was determined by inspection from the various recording gages (Fig. 1) and from the reports of the observers. Records of evaporation and temperature were obtained from the Class *A* evaporation station maintained by the Tennessee Valley Authority (TVA) at Murphy, N. C. A continuous stream-flow hydrograph was developed from the recorder charts of the rated U. S. Geological Survey recording stream gage at Tomotla.

FIG. 1.—MAP OF VALLEY RIVER IN NORTH CAROLINA

THEORY

Rainfall occurring over the natural river basin is assumed to be disposed of as follows:

(*1*) *Surface Loss.*—Surface loss is that part of the rain which is intercepted by the vegetal cover and natural or artificial retention basins from which it eventually evaporates and is thus prevented from entering the stream channels. This loss has been found to vary with the rainfall, being approximately constant for rains of the same amount. In other words, the greater the depth of rain the greater will be the quantity lost at the surface until a practical maximum is reached at some extremely high rainfall. Observation indicates that the full value of the potential surface loss is again available within a few hours after the end of a storm; therefore, whenever rains are separated widely enough to be analyzed independently, the full loss may be assumed for each rain. There is some indication that the amount of the surface loss is affected by the intensity of rainfall; but the complexity of the problem prevents a solution for the laws governing the variation. Storms occurring during flood season, which are considered herein, rarely reach extreme rates of rainfall and little error is introduced by the use of average values.

(*2*) *Field-Moisture Loss.*—Field-moisture loss is that part of the rain which is absorbed in the upper layers of the soil where it remains until removed by evaporation or transpiration. The potential field-moisture loss at any time is equal to the net amount of moisture taken from the soil by evaporation and transpiration since the last time the soil was saturated. The writers have used the accumulated evaporation from a standard evaporation pan as an index of field-moisture deficiency. It has been demonstrated that the moisture loss from the soil is greater during the first few days immediately after a rain than during the succeeding days, but the complexity of the problem precludes the determination of a variable coefficient for converting the pan evaporation to evaporation from the soil. There is a practical maximum that the field-moisture deficiency cannot exceed, and this value can be determined. Inasmuch as the storms of the flood season come at relatively short intervals, the use of an average coefficient introduces little error and reduces, considerably, the work involved in the use of the method.

(*3*) *Surface Runoff.*—Surface runoff is that part of the rain which travels across the ground surface to the nearest stream channel and thence to the main river system. The subsurface flow that travels through the upper layers of the soil to the stream channel is included with the surface runoff.

(*4*) *Ground-Water Accretion.*—The ground-water accretion is that part of the rainfall which percolates through the soil to the ground-water level. The resultant rise in the ground-water level causes an increased flow from the ground-water storage to the stream channel, until an amount equal to the accretion has drained into the stream channel.

ANALYSIS OF THE HYDROGRAPH

Stream-Flow Separation Charts.—The total loss for each storm studied was computed by subtracting measured runoff from observed average rainfall. Continuous discharge hydrographs were plotted to a scale 2,000 cu ft per sec to the inch vertically and two days to the inch horizontally (Fig. 2, at reduced scale). The average rainfall was plotted in block form on the same sheet, together with notes regarding snow on the ground or sub-freezing temperatures. These hydrographs were analyzed and the runoff measured by storms.

To aid in the complete separation of the hydrographs by storms, the following curves and relations were developed:

Ground-Water Recession Curve.—Fig. 3(*a*) is a ground-water recession curve plotted as the relation between ground-water flow at a given instant and the flow twenty-four hours later.[3] The curve is a composite of a large number of

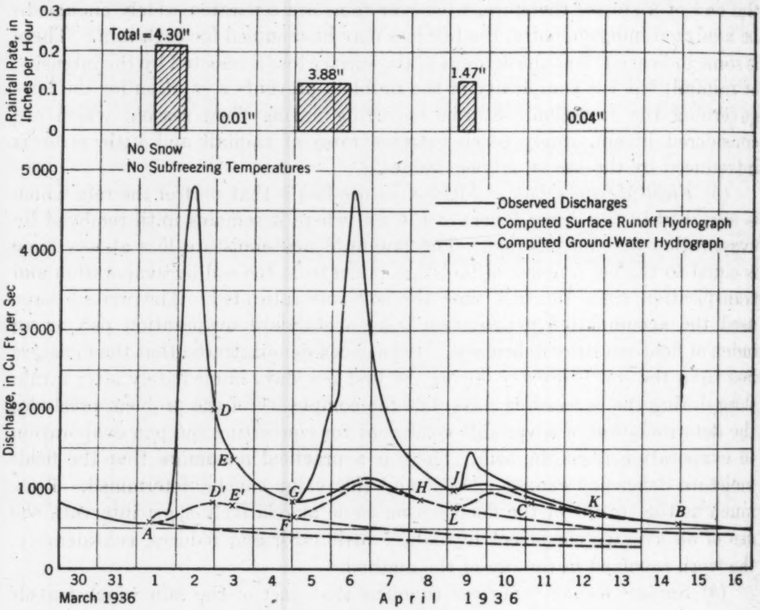

FIG. 2.—TYPICAL HYDROGRAPH

points from selected data for five years of record. The relation plots as a straight line on logarithmic paper and, for the range shown as a dashed line, represents an extension beyond the limit of these data. Care must be taken that the data selected for this curve are free of surface runoff. The duration of surface runoff may be taken as the length of the unit graph base or may be computed.[4]

Surface-Runoff Recession Curve.—Fig. 3(*b*) is a surface-runoff recession curve in a form similar to the ground-water recession curve. In this case the time increment was taken as twelve hours because of the higher rates of change involved. Data for this curve were obtained by drawing the ground-water hydrograph under the receding limbs of selected storm hydrographs by using

---

[4] "Synthetic Unit-Graphs," by F. F. Snyder, *loc. cit.*, Pt. 1, p. 447.

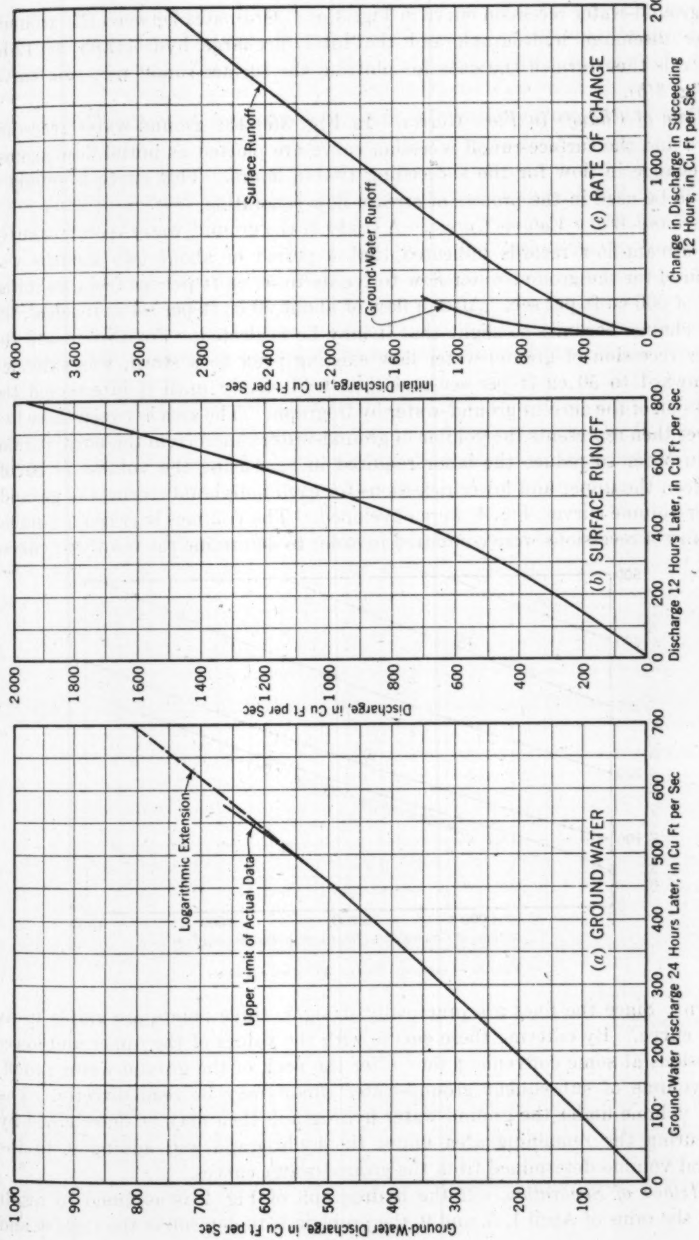

FIG. 3.—RECESSION CURVES

the ground-water recession curve in Fig. 3(*a*). Ordinates between the ground-water discharge hydrograph and the total discharge hydrograph at 12-hr intervals then furnish the data for plotting the surface-runoff recession curve in Fig. 3(*b*).

Rate of Change in Flow Curves.—In Fig. 3(*c*) the ground-water recession curve and the surface-runoff recession curve are plotted as initial flow against the change in flow for the succeeding twelve hours. This curve is purely a tool to be used in the process of stream-flow separation.

Ground-Water Volume Curves.—A study of the ground-water recession curve and stream-flow records indicated that a period of about two months was required for the ground-water flow to recede to 50 cu ft per sec from an initial flow of 500 cu ft per sec. After a flow of about 50 cu ft per sec is reached, the flow change becomes so slight that it may be neglected. For this reason the lower recession of ground-water flow existing prior to a storm was extended downward to 50 cu ft per sec and then held steady until it intersected the recession of the current ground-water hydrograph. The area between these two curves then represents the volume of ground-water runoff from the current rain.

In order to reduce the labor required in measuring the volume of runoff between the upper and lower recessions for each individual storm, the ground-water volume curves, Fig. 4, were developed. The volumes between a number of pairs of recessions were computed in order to determine the family of curves

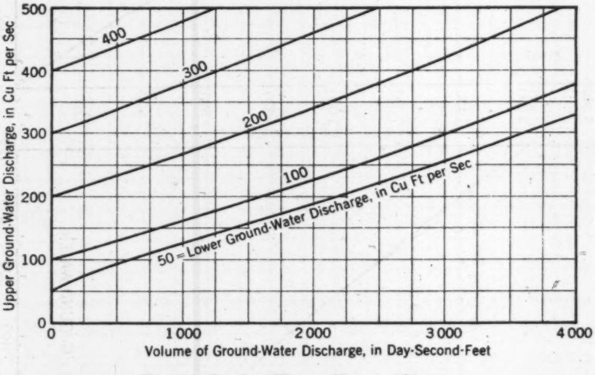

FIG. 4.—GROUND-WATER VOLUME CURVES

shown. Since the lines are practically straight, three points are ample to fix each curve. By entering these curves with the values of the upper and lower recessions at some convenient time after the peak of the ground-water runoff, the volume of subsequent ground-water runoff may be read directly. The total volume under the ground-water hydrograph then may be determined by measuring the remaining area under the hydrograph and adding it to the partial volume determined from the ground-water curves.

Method of Separation.—If the hydrograph of Fig. 2 is assumed to result from the rains of April 1, 5, and 9, the problem is to determine the surface and ground-water runoff for each rain. The ground-water recession that would have occurred if there had been no rain may be drawn by applying the ground-water recession curve (Fig. 3(*a*)), starting at point *A*. In a like manner the ground-water recession curve may be applied starting at point *B*, where the shape of the hydrograph indicates that the flow is entirely from ground water, and carried backward until it departs from the stream-flow hydrograph and reaches a point *C* somewhere near the estimated point of inflection of the falling limb of the total ground-water hydrograph. The remaining part of the ground-water hydrograph between *A* and *C* must be computed by another method.

The change in flow for the 12-hr period *D E* on the stream-flow hydrograph is the sum of the change in flow *D′ E′* of the ground-water recession and the concurrent change in the surface-runoff recession. If the ground-water flow at point *D′* is assumed, an approximate value for the change in ground-water discharge in the succeeding twelve hours may be obtained from Fig. 3(*c*). If this value is subtracted from the observed change in discharge, *D E*, the result is the change in surface runoff in twelve hours. By re-entering Fig. 3(*c*) with this rate of change of the surface runoff, the initial surface discharge, *D D′* may be determined. The value of ground-water flow at point *D′*, computed by subtraction, should agree with the assumed value. If this value is far different from the preliminary estimate, a recomputation is indicated. In this manner that part of the total ground-water hydrograph under the observed stream-flow recessions may be computed. Since the ground-water discharge comes to a peak considerably after the peak surface runoff, this method permits the computation of the peak ground-water flow. With this flow known, the rising limb of the ground-water hydrograph may be drawn in arbitrarily without introducing any appreciable error. The receding limbs of the ground-water hydrographs for the storms of April 1 and 5 may be drawn in with the ground-water recession curve starting at points *F* and *L* respectively. The computed ground-water flows for the storm of April 9 will join the recession near point *C* and the ground-water separation is complete.

Starting with the surface-runoff ordinate *G F*, the ordinates of the surface-runoff recession for the storm of April 1 may be computed from the surface-runoff recession curve (Fig. 3(*b*)) and added to the total ground-water discharge to give the recession *G H*. In a similar manner the recession *J K* for the storm of April 5 can be computed. The volume of ground water may be computed as outlined under the discussion of the ground-water volume curves. The volume of surface runoff may be measured on the hydrograph.

This method of stream-flow separation is based on the time characteristics of the stream flow. This is the classification of stream flow in common use today.

Supplemental Relations.—If selected isolated storms are attacked first with the preceding method of separation, certain data may be developed that will be helpful in the solution of the more complicated cases. The writers have developed several relations in the course of this study that can be used for further separation work or to predict the ground-water hydrograph in forecasting work. These relations are:

Total Runoff Versus Ground-Water Runoff.—Fig. 5 shows the relation between total runoff and ground-water runoff for the storms included in this study. A curve similar to this has been presented by other writers, but as yet no explanation or logical basis for the relation has come to the writers' attention. An attempt was made to determine an infiltration rate or rate of ground-water accretion in inches per hour, but the results varied so widely as to lead to the belief that no consistent rate existed. This belief was further strengthened when the relation shown in Fig. 5 was developed.

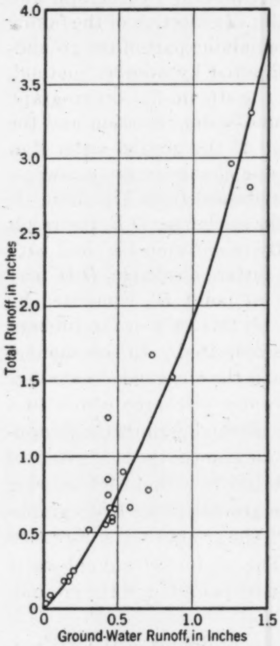

Fig. 5.—Total Runoff Versus Ground-Water Flow

Ground-Water Runoff Versus Net Peak Ground-Water Flow.—Fig. 6 presents the relation between the volume of ground-water runoff and the net peak height of the ground-water hydrograph.

Duration of Rainfall Versus "Time to Ground-Water Peak."—The relation between the duration of rainfall and time-to-peak ground-water discharge is shown in Fig. 7, as indicated by the data for the Valley River. "Time to peak" was computed from the beginning of rainfall.

Analysis of Rainfall Losses

Method.—The analysis of stream flow having been completed, it was possible to compute the total runoff from each individual storm and to determine the total rainfall lost. As outlined under the heading "Theory," this total loss is to be separated into surface loss and field-moisture loss. The problem of dividing this total loss into two parts, each governed by different factors and with all the governing relations unknown, does not lend itself to a direct mathematical solution. Therefore, a more philosophical method was used.

Based on the writers' observations in forecasting work and their knowledge of the area under consideration, preliminary assumptions were made for the variation between rainfall and surface loss. First assumptions for the relation between pan evaporation and soil evaporation were taken from standard texts on hydrology. Using these assumptions, the total losses for several entire flood periods were studied and the indicated adjustments were made to the basic assumptions so that the computed losses approximated the measured total losses for the periods.

With these revised assumptions the study of individual storms was begun. Immediately after a rain of several inches, or a series of lesser rains totaling several inches in a few days, the accumulated pan evaporation between successive rains was computed and multiplied by the assumed ratio between pan and soil evaporation. Adding to this value an estimated surface loss based on the amount of rainfall gave a computed value of the theoretical total loss for the storm. By comparing this computed value with the observed loss, in the light of all the available data, further readjustments of the assumed relations were made and certain other governing rules were established until, by successive approximations, relations that seemed to give the most consistent results were developed. The final relations developed were as follows:

Surface Loss.—As outlined herein under "Theory" the surface loss was found to be proportional to the amount of rainfall. Fig. 6 shows the relation developed for the Valley River Basin. This curve represents the final result of successive approximations which in combination with the final relations for field-moisture loss gives the lowest standard error of estimate for the data studied. The points plotted on the curve represent, for each storm studied, the difference between observed total loss and estimated field moisture loss as computed from the relations outlined under "Analysis of Rainfall Losses: Field Moisture Loss."

Field-Moisture Loss.—As stated under the heading "Theory" the writers have used the pan evaporation as an index of the field-moisture deficiency.

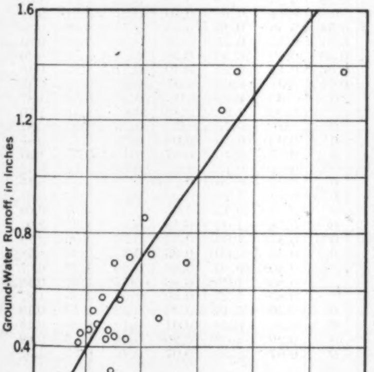

FIG. 6.—GROUND-WATER RUNOFF VERSUS NET PEAK GROUND-WATER FLOW

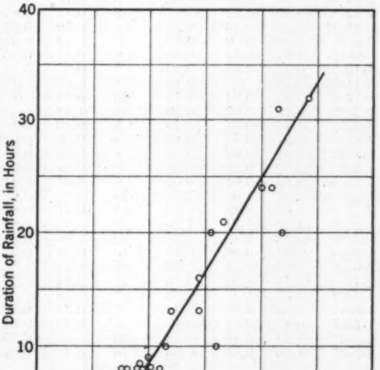

FIG. 7.—DURATION OF RAINFALL VERSUS TIME TO GROUND-WATER PEAK

It was found that the field-moisture deficiency at any time was equal to 0.9 times the total pan evaporation since the ground was last saturated, less any additions made to the field moisture by intervening rains. Studies of storms occurring after protracted dry spells showed that the total observed loss less surface loss averaged very close to 0.8 in. This value was taken as the maximum possible value of field moisture deficiency.

In the course of the study it was observed that for storms of short duration the observed loss less the estimated surface loss was often less than the available field-moisture deficiency despite the fact that there was an adequate volume of rainfall to satisfy the available deficiency. A further study of these cases showed that the difference between observed loss and estimated surface loss could be expressed very closely by 0.05 times the duration of the rain in hours.

TABLE 1.—TABULATION OF DATA AND COMPUTATION OF LOSS AND RUNOFF

[a] Maximum possible deficiency.

Application of Method.—Table 1 presents the data used in the study and a computation of the losses and runoff for these storms. Cols. 1 to 5 contain observed data obtained from rainfall records and the analysis of the hydrograph. The accumulated evaporation between storms multiplied by 0.9 is entered in Col. 6. The residual field-moisture deficiency existing at the end of the previous rain is given in Col. 7. The sum of these two values gives the total field-moisture deficiency at the beginning of the current storm in Col. 8. The maximum possible absorption by the field moisture in Col. 9 is equal to 0.05 in. multiplied by the duration in Col. 4. The estimated absorption in Col. 10 is equal to the total deficiency except where this is greater than the maximum possible absorption, in which case the latter value is used. The surface loss in Col. 11 is determined from the relation in Fig. 8 by entering with the rainfall for the storm shown in Col. 1. The sum of Cols. 10 and 11 gives the computed total loss in Col. 12 that may be compared with the actual loss in Col. 5. Total runoff in Col. 13 is obtained by subtracting the computed total loss from the rainfall in Col. 1.

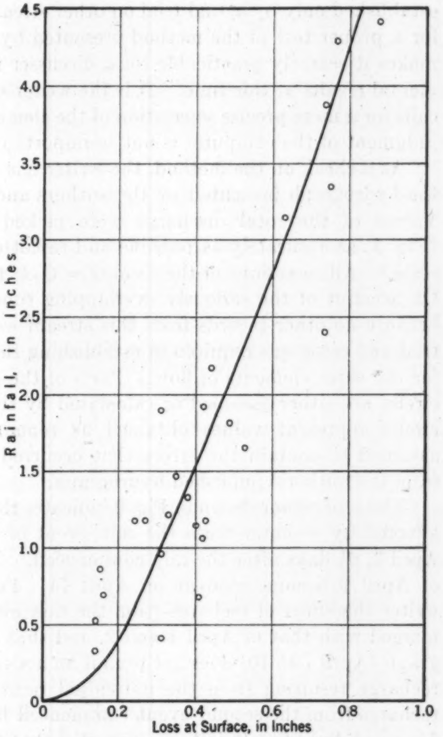

FIG. 8.—SURFACE LOSS CURVE

CONCLUSIONS

(1) The methods of stream-flow separation presented herein are satisfactory for the Valley River. By reducing the degree of personal judgment required in stream-flow analysis to a minimum, consistent results were obtained from all data studied.

(2) Accumulated evaporation from a standard evaporation pan is an index of field-moisture deficiency.

(3) Surface loss varies approximately with the amount of rainfall and appears to approach a practical maximum for high rainfalls.

(4) The methods of estimating runoff presented in this paper represent a distinct refinement over rainfall-runoff relations in which such third variables as initial flow, ground-water flow, or days to the last rain are used as criteria of runoff.

(5) Further study of a parallel nature is indicated in order to determine how these relations vary for other types of basins and for other seasons of the year. Perhaps further study on other basins will furnish data that will permit a greater refinement of the method. However, the average difference between measured and computed losses for the storms studied herein is only + 0.01 in., whereas the standard error of estimate is 0.10 in., which represents rather satisfactory accuracy for this problem.

DISCUSSION

Bertram S. Barnes,[5] Assoc. M. Am. Soc. C. E.—The general applicability of a forecasting procedure developed on one type of stream can be established only by actual trial on other streams. The length of time required for a proper test of the method presented by Messrs. Linsley and Ackermann makes it scarcely practicable for a discusser to present any conclusive experimental results at this time. It is the writer's belief, however, that the scheme calls for a more precise separation of the elements of flow, in which the personal judgment of the computer is not so important a factor.

As a check on the method, the writer has separated the elements of flow in the hydrograph presented by the authors and the results are shown in Fig. 9. Values of the total discharge were picked from the authors' hydrograph (Fig. 2) as accurately as possible and replotted, using a logarithmic discharge scale.[6] All recessions of the form $Q = Q_0 k^t$ therefore appear as straight lines. On account of the seriously overlapping runoff during this short period, and because no other records from this stream were at hand, a certain amount of trial and error was required in establishing the values of the depletion factor k for the three elements of flow. Parts of the graphs that are not marked with circles are either assumed or calculated by the use of k. Points indicated by circles represent values obtained as remainders, by subtraction, and are assumed to contain the errors that occurred in picking the discharge values from the authors' published hydrograph.

The separation shown in Fig. 9 indicates that the ground-water flow was not affected by recharge from the rain event of April 1 and 2 until midnight of April 7, 6½ days after the rain commenced. The recharge from the rain event of April 9 become evident on April 14. For some reason unknown to the writer the effect of recharge from the rain event of April 5 and 6 has become merged with that of April 1 and 2, and that part of the ground-water hydrograph (April 7 to 10) does not permit an accurate separation of the amounts of recharge resulting from the individual rains. It appears that the effect of recharge from the second event commenced between midnight of April 8 and 6 a.m. of April 9. It is to be expected that the higher ground-water level resulting from the first recharge would shorten the time lag of runoff from the second. However, the time lag for the beginning of runoff from the rain of April 9 was about 5½ days, with a higher initial ground-water level. As will be shown, the apparent total recharge was greater than could have been produced by either one of the two rain events alone unless the actual rainfall was materially greater than the value that the authors have obtained by Thiessen's method. The graph of net values of the ground-water event of April 7 to 10 is shown in Fig. 9 as a broken line. The curve of the first part of this graph can be extended to separate the two runoff events. If drawn with the maximum plausible curvature, it would give to the first event about one fourth of the total ground-water runoff for both events, and with a minimum curvature, the first event would receive about half the total, or 1.2 in. When comparing rainfall, runoff, and losses, it was found that, if the first event amounted to less than 0.92 in. or 38% of the total ground-water runoff for the two events, the second rain event would show no loss at all. With the assumed maximum value of 1.2 in. for the first event, the loss from the second rain would be about ½ in. or one third of the total for the two events. It is evident, therefore, that the greater loss occurred from the first rain.

[6] "The Structure of Discharge Recession Curves," by B. S. Barnes, *Transactions*, Am. Geophysical Union, 1939, Pt. IV.

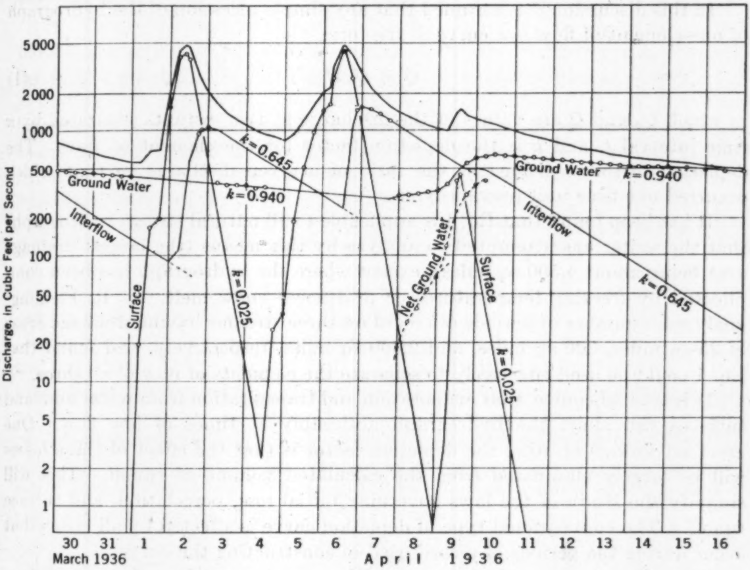

FIG. 9.—SEPARATION OF ELEMENTS OF FLOW, VALLEY RIVER AT TOMOTLA, N. C.

The names used by various writers to designate flows that are neither of ground water nor of surface origin have not been received with general approval. There is also some difference of opinion regarding the cause and nature of such flows. The writer now proposes the name "intermediate flow" or "interflow" and will use the latter term in the present discussion. It was the expressed intention of the authors to combine the elements of interflow and surface flow in the separation that they presented. A comparison of Fig. 2 with Fig. 9 indicates that they have actually included a large part of the interflow in their ground-water hydrograph. It also appears from Fig. 9 and the subsequent tabulation of data that the runoff from interflow is greater than that from surface flow.

It is the writer's opinion that interflows of appreciable amount should be given separate treatment in the forecasting of runoff, for two reasons. In the first place, the volume of interflow appears to be more closely related to the duration of rainfall than is the volume of surface flow or that of ground-water flow. Secondly, the inclusion of variable amounts of interflow with the other elements of flow interferes with the precise analysis of the hydrograph by the unit graph method, by the use of standard depletion curves, or by using the depletion factor.

In this discussion it is assumed that any simple recession of the hydrograph of one element of flow is a curve of the form

$$Q = Q_0 k^t \qquad (1)$$

in which Q_0 and Q are values of the discharge at two instants separated by a time interval t, and k is the depletion factor for the element of flow. The depletion factor is defined as the ratio of a given discharge to that which occurred one time unit previously.

It has been found that Eq. 1 is applicable to all natural stream hydrographs that the writer has attempted to analyze by this means (the largest drainage area being about 4,500 sq miles), except where the hydrograph has been complicated by freezing temperatures or protracted snow melt. J. R. Fleming[7] analyzed a number of periods of record on three streams having drainage areas of 25 sq miles, 320 sq miles, and 2,300 sq miles, respectively, and found that Eq. 1 could be used effectively to separate the elements of flow of all three.

It is true, of course, that evaporation and transpiration from water and land surfaces will affect the hydrograph noticeably at times of low flow. One great advantage of using the depletion factor is that the effect of these losses will be largely eliminated from the calculated volume of runoff. This will simplify the study of the laws governing initial loss, percolation, and surface runoff. The conventional type of depletion curve is affected by all losses that occur during the periods of record used in constructing the curve.

The volume of runoff, R, measured on a recession of an element of flow, is expressed as

$$R = \int Q \, dt \qquad (2)$$

Substituting the value of Q from Eq. 1, integrating, and applying the limits zero and T,

$$R = \int_0^T Q_0 k^t \, dt = \frac{Q_0 (k^T - 1)}{\log_e k} \qquad (3)$$

When Q_0 is the initial discharge and T is the duration of the period, Eq. 3 is the general expression of the volume of runoff during any period of the recession. Let an infinite time be substituted for T, and Q for Q_0, in Eq. 3. Since k is always smaller than unity, the equation becomes

$$R = \frac{-Q}{\log_e k} \qquad (4)$$

---

[7] "Analysis of Discharge-Recession Curves for Three Iowa Streams," by J. R. Fleming, unpublished thesis, State Univ. of Iowa, 1941.

Eq. 4 is the expression of the quantity of water (of one element—surface, interflow, or ground water) remaining in storage at any instant during the recession. It is solved by assigning to k its proper value for the element of flow that is being considered, and evaluating Q.

The total volume of water that a given rain event contributes to one element of flow may be calculated from the hydrograph as follows:

(1) Determine the hydrograph of the element of flow by graphical analysis, tabular computation, or a combination of the two. This graph should be drawn to a point that is past the peak and far enough down the recession limb so that Eq. 1 is applicable. Subtract the amounts of flow that are the result of previous rain events. These may be calculated by the use of logarithms, or the previous recession may be prolonged as a straight line on semilogarithmic paper and the values picked off directly. The depletion factor k is evaluated by taking values of Q at any two points on the recession.

$$\text{Log}\, k = \frac{(\log Q_1 - \log Q_2)}{T} \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which T is the elapsed time between the two points selected. In this discussion, one day will be used as the unit of time.

(2) Select a point on the hydrograph that is well past the peak of the event and definitely on the recession limb. Calculate the net runoff up to that point in the usual manner by the summation of values of $Q\,t$ for periods of one hour, one day, or any other convenient basis. In Eq. 4, substitute for Q the ordinate of the discharge hydrograph at the point selected and determine the value of R. Add the result to the volume of runoff previously computed for the initial part of the event. The sum will be the total volume of water that the storm has contributed to that element of flow.

The results of the foregoing analysis, compared with that of the paper, are presented in Table 2 with those obtained by the authors. The values of the depletion factor k were found to be as follows: Surface flow, $k = 0.025$; interflow, $k = 0.645$; and ground-water flow, $k = 0.940$. It is probable that a more accurate determination of these values could have been made if a longer period of record than 18 days had been used. The consistent plotting of the remainders in Fig. 9 indicates that the adopted values are sufficiently accurate for the present purpose.

TABLE 2.—TABULATION OF DATA AND COMPUTATION OF LOSS

(Quantities of Water are Expressed in Inches)

Date (April, 1936)	Rainfall	Duration (hours)	Runoff, surface (writer)	Runoff, interflow (writer)	RUNOFF, GROUND WATER		RUNOFF, SURFACE PLUS INTERFLOW		RUNOFF, TOTAL		LOSS	
					Author	Writer	Author	Writer	Author	Writer	Author	Writer
1...........	4.30	20	0.98	0.96	1.24	(1.1)	1.71	1.94	2.95	(3.04)	1.35	(1.26)
5...........	3.88	32	1.17	1.23	1.38	(1.3)	1.42	2.40	2.80	(3.70)	1.08	(0.18)
Total, 1 and 5....	8.18	52	2.15	2.19	2.62	2.40	3.13	4.34	5.75	6.74	2.43	1.44
9...........	1.47	10	0.07	0.08	0.70	0.19	0.09	0.15	0.79	0.34	0.68	1.13
Total, 1, 5, and 9.	9.65	62	2.22	2.27	3.32	2.59	3.22	4.49	6.54	7.08	3.11	2.57

Quantities enclosed in parentheses depend upon an assumed amount of 1.1 in. for the ground-water runoff resulting from the rain of April 8 and 9. This value has previously been shown to lie between 0.92 in. and 1.2 in. The total amounts of runoff and loss shown in Table 2 are those resulting only from the three rain events listed. Two other small rains occurred during the period but are assumed to have produced no runoff or recharge to ground water. There was also runoff resulting from precipitation that occurred previous to March 30. At midnight of March 29 there was an interflow of 330 cu ft per sec, corresponding to an amount of 0.25 in. in storage. It seems likely that this flow resulted from the thawing of frost in the soil or of snow in gullies and depressions. There was a ground-water flow of 480 cu ft per sec, corresponding to an amount of 2.61 in. in storage.

The storage equation may be applied to these data, using the form:

$$\text{Rainfall} - \text{runoff} - \text{loss} = \text{change in contents} \qquad (6)$$

The total loss shown in Table 2, therefore, may be checked with reasonable accuracy by the following summary, using storage values determined by Eq. 4:

Description	Loss (inches)
Total rainfall, March 30 to April 16, inclusive	9.70
Total runoff, March 30 to April 16, inclusive	7.42
Amount in storage at midnight, March 29	2.86
Amount in storage at midnight, April 16	2.54
Decrease in storage, March 30 to April 16, inclusive	0.32
Total loss, March 30 to April 16, inclusive	2.60

The writer believes that the suggestions contained in this discussion will not only simplify the work required in forecasting by methods similar to that presented by the authors, but will also eliminate, to a large extent, the errors arising from personal judgment in separating the elements of flow. The precise separation of the three elements should make each of them more readily predictable in amount. Whenever two elements of flow are added together in unknown proportions, the forecasting of their total amount and rate of depletion is necessarily complicated and uncertain, especially since a set of natural conditions favorable to a large flow of one element will not necessarily favor a large flow of either of the others.

Specifically, the application of the principle of the depletion factor would make straight lines of the curves given in Fig. 3. The slope of each line would be equal to the reciprocal of the appropriate depletion factor. It has been the writer's experience that ground-water curves of the type shown in Fig. 3(*a*), when extended downward to zero discharge, do not ordinarily pass through the origin. This fact suggests that if today's ground-water flow were zero, tomorrow's would be negative; that is, if any water were to be introduced into the stream channel tomorrow, it would be subject to a loss into the stream bed.

Likewise, Fig. 4 would become a single straight line with values of the net increment of ground-water discharge for its ordinates and recharge to ground-water storage for abscissas. Similar diagrams could be drawn for surface flow and interflow, but such diagrams would have to be used with care and skill in order that the proper allowance might be made for runoff occurring previous to the peak.

The authors' procedure of separating initial loss into two parts—surface loss and field-moisture deficiency—and comparing the latter with losses from an evaporation pan, is a distinct departure from any previous practice known to the writer. It is believed that the plan merits trial under various conditions of climate, soil, agricultural development, and topography. The degree of development of growing plants, especially annual crops, may have to be considered when comparing evaporation and transpiration from a natural watershed with the measured evaporation from a standard pan.

Richard Van Vliet,[8] **Esq.**—Some of the factors that enter into the so-called water-loss curve have been evaluated in this paper. Water-loss curves based on monthly or seasonal rainfall have been used for a number of years by hydrologists in studying the yield of drainage basins. The authors have developed such a curve for the Valley River, based on individual stream rises. The writer wishes to comment on a few of their conclusions.

The authors refer to one of the ways by which rainfall is disposed of as "surface loss" which, as defined by the authors, is in reality the sum of two quantities—interception and depression storage.[9] In order to determine these quantities separately, a study of the storm rainfall pattern is required. It cannot be done with any degree of success by considering only the total amount of storm rainfall and duration. The volume of interception and depression storage depends on rain intensity. Interception occurs at all rainfall intensities, whereas depression storage cannot occur unless the rate of rainfall is greater than the infiltration capacity. The authors state that "surface loss" becomes constant at some extremely high rainfall, but this is true only if the particular "high rainfall" is equal to the infiltration capacity. Excluding infiltration, interception becomes constant at very moderate rain intensities after interception storage is filled. This paper is a study of surface runoff phenomena, and in such a study the rainfall must be considered in detail, in regard to both its intensity and duration.

The authors state that the duration of surface runoff may be taken as the length of the unit graph base. From analyses of various stream rises, together with the corresponding channel inflow graphs, it has been found that direct surface runoff ends at about the point of inflection on the recession side of the hydrograph of a stream rise.[10] Beyond the point of inflection the recession side of the hydrograph is composed of two items—channel storage and ground water. The area under the recession side of the hydrograph beyond the point of inflection and above the ground-water flow curve is usually referred to as "channel storage." The use of the term "surface-runoff recession curve" by the authors to express this quantity is deemed unfortunate, as the term "channel storage recession curve" is generally used to express this quantity, since surface runoff has ended. Attention is called to the fact that the method of developing channel storage recession curves was first published by Robert E. Horton,[10] M. Am. Soc. C. E.

In Fig. 7 the authors correlate "duration of rainfall, in hours," with "time to ground-water peak, in hours." A study of the paper leads to an understanding that duration of rainfall is the total duration of storm rainfall, including any residual rainfall (rainfall in which the intensity is less than the infiltration capacity). The writer cannot agree with the authors that this relation holds true for all cases if total rainfall is accepted under their definition. For example, consider two storms, each having identical periods of rainfall excess of 1-hr duration; that is, with rainfall intensity greater than infiltration capacity. In one storm, however, assume also a period of residual rainfall in which the intensity is, say, 0.05 in. per hr, or well below the infiltration-capacity rate, and lasting for 4 hr. In the first storm the duration of rainfall is 1 hr and in the latter storm 5 hr. Other factors being equal, the time at which the ground-water flow will reach its peak will be practically the same for both storms. It seems to the writer that any attempt to correlate total duration of rainfall with time for ground water to reach its peak will give results of little value if the total duration of rainfall includes the period of residual rainfall.

LeRoy K. Sherman,[11] **M. Am. Soc. C. E.**—The quantity of moisture in the soil materially governs the intake of rainfall and consequently affects the quantity of surface runoff. Several empirical procedures have been used to approximate this important antecedent soil-moisture index. The writer[12] and others have based their approximations on percentage of antecedent rainfalls together with the intervening amounts of "drying out" time. The authors have estimated the amount of "drying out" with the logical and more specific use of an evaporation factor.

TABLE 3.—CHECK COMPUTATIONS OF LOSS AND RUNOFF[a]

Date	Rainfall (1)	− Surface runoff (2)	= Infiltration and initial loss (A)	Ground-water runoff (3)	+ Absorption (10)	+ Surface loss (11)	= Infiltration and initial loss (B)	Difference (Col. A minus Col. B)
2-13-35	1.19	0.14	1.05	0.42	0.20	0.34	0.96	−0.09
2-14-35	1.66	0.37	1.29	0.53	0.23	0.42	1.18	−0.11

[a] The column numbers correspond with those in Table 1.

In Table 1 the usual practice of segregating base flow, or ground-water flow, and surface runoff has not been followed. Apparently the authors assume that ground-water runoff (Col. 3) is due to infiltration, not absorbed

---

[12] "The Unit Hydrograph and Its Application," by L. K. Sherman, *Journal*, Associated State Eng. Societies, April, 1941, p. 4.

(Col. 10), and that this ground-water runoff all comes from the given storm on the basin. This may or may not be true. Ground-water runoff may originate, in part, from territory outside of the basin. A part of the ground-water flow may be measured by the stream gage and a part of this flow may by-pass the gage in transit through the soil. It is possible to check the assumption made in this case.

In Table 3 the writer has selected, at random, eight storms from Table 1. If the ground-water runoff is all accounted for in the manner assumed by the authors, then the figures in Col. B will equal the corresponding figures in Col. A. The column of differences A − B is the error in the authors' assumption, predicated upon correctness of computed absorption and surface loss. For a pioneering job this showing is not bad. It indicates that in this particular basin the authors' assumption as to ground-water flow and origin is correct. The authors have not made use of the more recent concepts of the infiltration theory, such as rainfall excess, the recession curve, and the mass curve of infiltration capacity. The writer used a few of the authors' antecedent soil moisture figures in such tests, but the number so used was not sufficient to draw any conclusions.

Further research, on the derivation of initial soil moisture along the lines suggested by the authors, is much needed in applied hydrology.

Franklin F. Snyder,[13] **Assoc. M. Am. Soc. C. E.**—A concise description of detailed studies of rainfall and runoff relations is presented in this paper. The methods followed give computed values of runoff that agree quite favorably with the observed values for the storms studied.

The methods of analysis followed and relationships developed are quite similar to those used in the Pennsylvania hydrologic investigations[14] for development of flood forecasting procedures and used by the writer[15] to compute a year's record of runoff from rainfall for a 1,147-sq-mile drainage area with no reference to observed stream flow. The authors have used pan evaporation as an index of soil moisture variation, whereas time and temperature were used for that purpose in the studies just mentioned.

There is one striking difference either in conception or in nomenclature: The writer believes that the author's "surface loss," which consists of by far the greater part of the difference between rainfall and runoff for the storms listed in Table 1, is really accretion to soil moisture and that the loss classified as addition to field moisture is probably an initial or surface loss. The most convincing indication of this is a comparison of pan evaporation and surface loss for periods of time for which complete data are given in Table 1.

For all except four of the storms listed the surface loss (Col. 11) is greater than the values in Col. 6 (0.9 × accumulated evaporation). For the period including the storms of January 4, 1936, to February 17, 1936, the total surface loss is 2.77 in. and the total evaporation is 0.70 in. $\left(\frac{0.63}{0.9}\right)$. Surface loss is defined in the paper (see heading "Theory: (1) Surface Loss") as "that part of the rain which is intercepted by the vegetal cover and natural or artificial retention basins from which it eventually evaporates and is thus prevented from entering the stream channels." It is difficult to understand how this surface loss by evaporation can be four times the observed evaporation from a pan or how there can be enough natural or artificial surface retention basins to store 2.07 in. (2.77 − 0.70) for later evaporation. For a longer or a more rainy period, the procedure followed might call for a still larger amount of surface storage. The writer believes that a considerable part of this rainfall became soil moisture.

[14] "Report of Cooperative Hydrologic Investigations," by Pennsylvania Dept. of Forests and Waters, U. S. Geological Survey, and U. S. Weather Bureau, Commonwealth of Pennsylvania, August, 1939.

[15] "A Conception of Runoff Phenomena," by Franklin F. Snyder, *Transactions*, Am. Geophysical Union, 1939, Pt. 4, pp. 725–738.

In 1937 the writer made extensive studies of rainfall and runoff relations for storms occurring in the period October, 1934, to September, 1936, on the Hiwassee River Basin above Reliance, Tenn., which includes the Valley River studied by the authors. Using what seemed to be rational values of evaporation and transpiration, a maximum value of 4.0 in. of accumulated soil moisture above a base of 0.00 was obtained in March for the winter of 1934–1935 and 7.5 in. in February for the winter of 1935–1936. At the time it was concluded that the water went to soil moisture rather than deep seepage since the method of computing evaporation and transpiration reduced the accumulated values of soil moisture to the assumed base of 0.00 in. in what appeared to be a reasonable manner during the succeeding summers. These values of variation in soil moisture are much greater than the maximum possible value of 0.80 in. field-moisture deficiency assumed by the authors. This value of 0.80 in. would appear to be a more reasonable maximum value of surface loss.

There is also some question as to the general applicability of the empirical value of 0.05 in. per hr maximum possible absorption. This criterion controls the values of estimated absorption for seven of the first eight storms listed in Table 1, all in February or March of 1935, and does not control in any of the other storms. Better results would have been obtained if the assumed maximum rate of absorption had been larger for the first three storms concerned (the storm of February 14, 1935, is not involved) and smaller for the last four storms. This indicates that the rate decreased with a continuation of frequent rains.

The question raised as to nomenclature and definitions does not invalidate the very good results obtained by the authors, but it would be of considerable importance to someone trying to apply the procedures to other areas.

Ray K. Linsley, Jr.,[16] **and William C. Ackermann,**[17] **Juniors, Am. Soc. C. E.**—The response to this paper presenting a new method of runoff prediction is gratifying. Several helpful suggestions have been made.

The writers are quite in agreement with Mr. Barnes' statement that a more precise determination of the runoff associated with a given storm event would aid considerably in the solution of the entire problem. It is unfortunate that no better data were available for Mr. Barnes to check the writers' figures than the small-scale hydrograph published with the paper. The differences shown in Table 2 between his values of runoff and those computed by the writers may result from slight errors in the published hydrograph as a result of several drafting operations incidental to publication.

---

[16] Asst. Hydrologic Engr., U. S. Weather Bureau, Sacramento, Calif.

[17] Asst. Hydr. Engr., TVA, Knoxville, Tenn.

The writers have attempted to analyze hydrographs of several streams in the Tennessee Valley by the procedure suggested by Mr. Barnes. The results were not sufficiently consistent to justify the inclusion of a third runoff element.

Mr. Barnes suggests that the depletion curve of Fig. 3(*a*) should not pass through zero. The curve actually becomes tangent to a 45° line at 50 cu ft per sec, indicating that for ground-water flows of 50 cu ft per sec or less there is no change in flow from day to day.

Mr. Van Vliet questions the writers' failure to include rainfall intensity as a factor in their analysis. This is due primarily to the requirement that river forecasting procedure be simplified to the point where the maximum accuracy is achieved in the time available to the user. The lengthy job of working up hourly rainfall amounts is beyond the scope of such work. Moreover the determination of hourly average rainfall amounts for basins of a hundred square miles or larger is difficult and possible of only approximate solution at best. The use of a limiting rate of absorption in inches per hour, however, does recognize the importance of considering duration or average rate of rainfall for each storm event.

Mr. Van Vliet is correct in stating that depression storage cannot occur unless the rate of rainfall exceeds the infiltration capacity. In a natural stream basin the infiltration capacity will vary from point to point with values of zero at some points. Depression storage therefore can begin to accumulate almost with the first drops of rain. As the rain continues the depressions will gradually fill, and if a sufficient volume of rain falls in a single storm they will fill to a point where no additional water can be accommodated. It was on this basis that the writers state that surface loss—that is, depression storage and interception loss—increases with increasing volume of rainfall until, for high amounts of total rainfall, a practical maximum possible detention is reached.

The writers' statement (see "Analysis of the Hydrograph: Ground-Water Recession Curve") that "The duration of surface runoff may be taken as the length of the unit graph base * * *" is not correctly worded. It should have read "The duration of outflow of surface runoff at the gaging station may be taken as the length of the unit graph base." The term "surface runoff recession" was chosen because the recession curve so designated includes only that portion of the channel storage which, in the writers' opinion, was derived from surface runoff. Undoubtedly some improvement in standard terminology would be of great value to the entire problem of rainfall and runoff study.

Throughout the paper the duration of runoff used was an estimated effective value derived by averaging the approximate durations of the mass of the rainfall at the various stations. Insignificant amounts before or after the main storm were not included in the determination.

Mr. Snyder's comments on the definition of surface loss given by the writers are partly correct. Evaporation from depression storage and interception could only account for a portion of the computed surface loss and the balance must go into soil moisture. The value of 0.8 in. for the maximum possible soil moisture deficiency was based on data from relatively few storms. However, additional studies of numerous summer storms indicate a value of 1.0 in. which is a rather close check on the original figures. This should be considered as a maximum soil moisture deficiency possible through evaporation rather than as a total possible volume of soil moisture that the basin is capable of retaining.

The method of determining the surface and field moisture loss was by trial and error to find the values which best fit the theory. The exact distribution of the losses from the storms studied will probably never be known. That portion of the loss which appears to vary with volume of rainfall does not seem to be attributable logically to field moisture absorption. Conversely it would not appear logical that evaporation is an index of interception capacity of depression storage.

Subsequent to the publication of the paper, the study was duplicated independently using data from a large number of summer storms on the Valley River Basin. The results obtained agreed quite closely with those of the original study. The results for the four important factors used in the proposed method are as follows:

Evaporation Factor.—The factor of 0.9 was not changed.

Surface Loss.—The surface loss curve derived was shifted laterally about 0.05 in. to the right. This change may indicate more interception during the summer months although the change is too small to be conclusive.

Maximum Possible Field Moisture Deficiency.—As stated elsewhere in this discussion, a value of 1.0 in. was determined for this factor. This value is probably more reliable than the earlier value of 0.8 in. since more data were available for study.

Maximum Possible Rate of Absorption.—The rate of absorption seems to be about 0.10 in. during the first hour of a storm, decreasing until the average rate of 0.05 in. per hr applies for storms of 12 hr or longer. Improvement in the definition of this rate results from the large number of short-duration storms included in the summer data. There is some likelihood that these rates change from storm to storm as Mr. Snyder suggests. The writers made no attempt to determine this rate quantitatively since the change seems to be rather small in any case.

In closing, the writers wish to thank those who contributed to the discussion of this paper. It seems likely that a real test would come only from carefully conducted experiments on additional watersheds with adequate rainfall and runoff records, a central evaporation station, and sufficient field surveys to observe the soil conditions thoroughly.

Paper No. 2148

THE SUSPENSION BRIDGE TOWER CANTILEVER PROBLEM

BY BLAIR BIRDSALL,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. FRANCIS P. WITMER, JOHN I. COPP, AND BLAIR BIRDSALL.

SYNOPSIS

A generalized theory is offered in this paper for the study of the behavior of suspension bridge towers under the action of forces in a plane parallel to the axis of the bridge.[2] Reduced to its essentials, the structure under consideration is a vertical cantilever, of variable cross section, with a fixed base. The top of the cantilever is free to rotate, and is deflected by means of a horizontal and a vertical load. The usual problem is to find the horizontal tower-top force required to produce a certain deflection in conjunction with a given vertical tower-top load. As soon as the horizontal force has been found, it is a simple matter to find any other properties of the deflected tower, such as the elastic curve or the stresses.

The theory for the so-called "General Case" includes the effect of the weight of the tower as a producer of bending moment in the deflected tower, as well as the effect of an eccentrically placed tower-top load and eccentric loads at the roadway level. (In a mathematical sense, the true general case has not been used in the body of this paper, as the emphasis is on practical application. Thus, the so-called "General Case" presents the tools by means of which the true general case may be approached as nearly as necessary to produce what the writer considers to be a sufficient degree of accuracy for the most complicated case ordinarily encountered in practice.) Simplifications of the "General Case" for many special cases are either given in detail or outlined.

The results of applying the theory to three tower shafts are used as a means of indicating the accuracy of several approximate methods which may be used as practical tools for solving this problem if the precision of the mathematical treatment is not required.

NOTE.—Published in April, 1941, *Proceedings*.

[1] Asst. Chf. Engr., Bridge Dept., John A. Roebling's Sons Co., Trenton, N. J.

[2] The more detailed study from which this paper was prepared has been placed on file for reference at Engineering Societies Library, 33 West 39th Street, New York, N. Y.

INTRODUCTION

The mathematical principles underlying the development of this theory are not new. In 1882 the late S. W. Robinson,[3] M. Am. Soc. C. E., published the general solution of the differential equation for bending moment in a beam or column caused by combined transverse and axial loads. The method of solution for this type of equation (linear differential equation with constant coefficients) may be found in any book on differential equations. The salient features of the application of the general solution to the problem of flexure and direct stress have been summarized by Francis P. Witmer,[4] M. Am. Soc. C. E. The applications of the general solution to some of the cases included in this paper have been published[5] in a standard textbook.

In this paper, the writer has attempted to make a comprehensive presentation of the subject, combining the fundamental theory for handling the problem under any combination of loads with a description of some practical short-cut methods, for the use of both the student and the practicing engineer.

OUTLINE OF THE PROBLEM AND DEFINITION OF SYMBOLS

The problem consists of finding the horizontal load required to produce a desired deflection at the top of a vertical, fixed-base cantilever which is acted upon by certain known vertical loads. The conditions of the problem are illustrated by Fig. 1. All loads are expressed in pounds, all dimensions in feet, and all moments in pound-feet. Other definitions are:

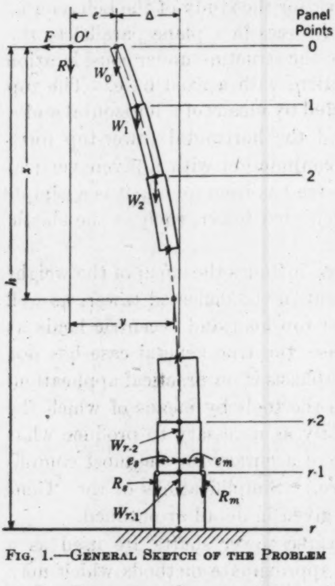

FIG. 1.—GENERAL SKETCH OF THE PROBLEM

F = desired horizontal tower-top load;

R = known vertical external load (cable reaction) on tower top;

e = eccentricity of R with respect to center line of top of tower;

Δ = known required deflection of tower top;

$0, 1, 2 \cdots (r-1), r$ = panel points along the center line of tower at which there are changes in moment of inertia, or known concentrated loads, or both;

$W_0, W_1, \cdots W_{r-1}$ = parts of tower weight assumed to be concentrated at the panel points indicated by the subscripts;

R_s, R_m = reactions on tower at roadway level;

---

[3] "Strength of Wrought Iron Bridge Members," by S. W. Robinson, Van Nostrand Science Series, No. 60, D. Van Nostrand, Publisher.

[4] "Basic Formulas for Combined Flexure and Direct Stress," by Francis P. Witmer, *Civil Engineering*, December, 1937, p. 855.

[5] "Modern Framed Structures," by the late J. B. Johnson, C. W. Bryan, Members, Am. Soc. C. E., and F. E. Turneaure, Hon. M. Am. Soc. C. E., Pt. II, 10th Ed., John Wiley & Sons, Inc., p. 278.

e_s, e_m = eccentricity of roadway reactions with respect to center line of tower at that point;

x_1, x_2, $\cdots$ x_{r-1}, x_r = known vertical distances from tower top to panel points;

y_1, y_2 $\cdots$ y_{r-1}, y_r = ordinates to panel points from line of action of R;

S_a = length of panel between panel points $a - 1$ and a;

h = total height of tower;

I_a = moment of inertia (in²-ft²) of the tower shaft between panel points $a - 1$ and a;

E = modulus of elasticity of tower material (pounds per square inch);

M = bending moment;

A, B, D, and C = constants determined from the loading conditions; and

G_a, K_a = integration constants for the panel between points $a - 1$ and a.

Basic Assumptions.—Six basic assumptions should be kept in mind:

1. All vertical distances remain constant;
2. Shear deformation is zero;
3. The tower base is rigidly fixed;
4. The tower weight is applied as a series of concentrated vertical loads;
5. The tower shaft is made up of a series of panels in each of which the moment of inertia is constant; and
6. The moment arm of R does not change due to rotation of the tower top.

The deflections and deformations are so small in comparison with the vertical dimensions that the error introduced by Assumption 1 is negligible. The heaviest concrete pier will yield to a certain extent, but the deflecting load and tower moments based on Assumption 3 will be on the side of safety. In Assumption 4 the concentrations are placed at the points of change in moment of inertia. However, the weights can be applied at any points without affecting the method of solution. The labor of computation would be increased, however, as each concentration as well as each change in moment of inertia requires an additional pair of integration constants unless they occur at the same point.

The Problem.—

Given: All external loads except deflecting load F; all physical characteristics of the tower shaft; and all dimensions, including the deflection Δ, except the ordinates to the elastic curve.

To Find: The deflecting load F, the ordinates to the elastic curve, and any other desired information, such as the bending moments, the stresses, or the tangents to the elastic curve.

THE DIFFERENTIAL EQUATION

From elementary mechanics, the general differential equation for bending moment is

$$\frac{d^2y}{dx^2} = \frac{M}{E\,I} \qquad (1)$$

The moment due to the type of loading contemplated in this paper may be expressed as follows:

$$\frac{M}{E\,I} = \pm A\,y \pm B\,x \pm D\,x^2 \pm C \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which the sign depends on the direction of rotation. The function of x represents the moment due to transverse loads or any other moment which is independent of the ordinate y, and no combination of transverse loads can lead to a higher power of x than the second. The product $A\,y$ represents the moment due to axial loads. There will be no higher power of y than the first as long as concentrated loads only, and not distributed loads, have moment arms that depend on the ordinate y.

In order to determine the proper signs, assume that the cantilever of Fig. 1 is rotated 90° in a counterclockwise direction, and place the origin of coordinates at O'. By the usual convention, it is apparent that the column carries negative moment. Any load to the left of a section, which has a counterclockwise direction of rotation about the neutral axis of the section, helps to produce the negative moment.

Thus, since the predominating axial loads have counterclockwise moments about sections of the tower to the right of the points of application of these loads, the resulting sign of $A\,y$ must be negative. Since y is positive, however, A must be negative, and the term, as it appears in Eq. 2, is $-A\,y$. Since x is always positive, the same reasoning applies to all other terms, and Eq. 2 becomes:

$$\frac{d^2y}{dx^2} = \frac{M}{E\,I} = -A\,y - B\,x - D\,x^2 - C \ldots (3)$$

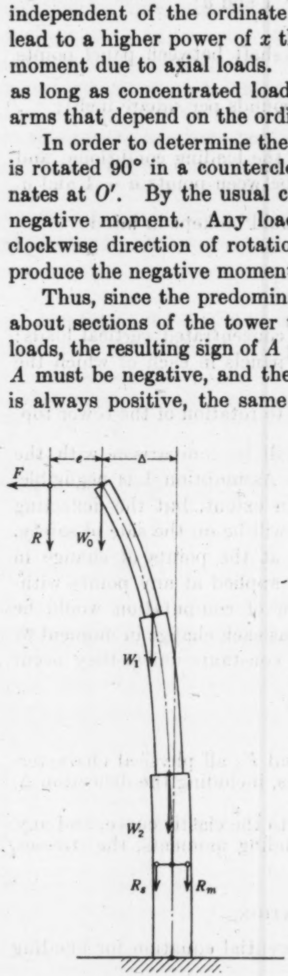

FIG. 2.—THE "GENERAL" CASE

It is shown elsewhere[4] that, in general, the term for the axial loads is negative for loads producing compression, and positive for loads producing tension, and that the signs of the terms for the transverse loads depend on the direction of rotation. The general solution of Eq. 3 is:

$$y = -\frac{K}{A}\sin x\sqrt{A} - \frac{G}{A}\cos x\sqrt{A} - \frac{D}{A}x^2 - \frac{B}{A}x + \frac{2\,D}{A^2} - \frac{C}{A} \ldots\ldots (4)$$

The formal derivation of this solution is given in Appendix I of the complete paper.[2] Expressions for slope, bending moment, and shear may be found in terms of the independent variable x by taking successive derivatives of Eq. 4; thus—

Slope of the elastic curve:

$$\frac{dy}{dx} = -\frac{K}{\sqrt{A}}\cos x\sqrt{A} + \frac{G}{\sqrt{A}}\sin x\sqrt{A} - \frac{2\,D}{A}x - \frac{B}{A} \ldots\ldots\ldots (5)$$

bending moment:

$$E\,I\,\frac{d^2y}{dx^2} = E\,I\left(K\sin x\sqrt{A} + G\cos x\sqrt{A} - \frac{2\,D}{A}\right)\ldots\ldots\ldots(6)$$

shear:

$$E\,I\,\frac{d^3y}{dx^3} = E\,I\,(K\sqrt{A}\cos x\sqrt{A} - G\sqrt{A}\sin x\sqrt{A})\ldots\ldots\ldots(7)$$

THEORY

The "General" Case; Variable Moment of Inertia, Eccentricity at Tower Top, Tower Weight and Eccentric Roadway Loads Considered.—To simplify the presentation, a tower shaft having three different values of I is used. The roadway loads are placed at a section that lies within the lowest of the three tower divisions. The problem is illustrated by Fig. 2.

For this case, four equations of the following form are obtained from Eqs. 3 and 6:

$$\frac{d^2y}{dx^2} = -\,n_a^2\,y - B_a\,x - C_a = K_a\sin n_a\,x + G_a\cos n_a\,x\ldots\ldots(8)$$

The conditions of the problem yield the following values for the loading constants of Eq. 3: With $D = 0$ in all panels, let $A = n^2$; then,

$$\left.\begin{aligned}
A_1 &= \frac{R + W_0}{E\,I_1} = n_1^2, \quad B_1 = \frac{F}{E\,I_1}\\
A_2 &= \frac{R + W_0 + W_1}{E\,I_2} = n_2^2, \quad B_2 = \frac{F}{E\,I_2}\\
A_3 &= \frac{R + W_0 + W_1 + W_2}{E\,I_3} = n_3^2, \quad B_3 = \frac{F}{E\,I_3}\\
A_4 &= \frac{R + W_0 + W_1 + W_2 + R_s + R_m}{E\,I_3} = n_4^2, \quad B_4 = B_3\\
C_1 &= -\,\frac{W_0\,e}{E\,I_1}\\
C_2 &= -\,\frac{W_0\,e + W_1\,y_1}{E\,I_2}\\
C_3 &= -\,\frac{W_0\,e + W_1\,y_1 + W_2\,y_2}{E\,I_3}\\
&\text{and}\\
C_4 &= -\,\frac{W_0\,e + W_1\,y_1 + W_2\,y_2 + R_s\,y_3 - R_s\,e_s + R_m\,y_3 + R_m\,e_m}{E\,I_3}
\end{aligned}\right\}\ldots(9)$$

By Eq. 5, for this case, there are four equations of the following form for the slope of the elastic curve:

$$\frac{dy}{dx} = -\,\frac{B_a}{n_a^2} - \frac{K_a}{n_a}\cos n_a\,x + \frac{G_a}{n_a}\sin n_a\,x\ldots\ldots\ldots\ldots(10)$$

The eight equations of the form of Eqs. 8 and 10 (one formula for moment and one for slope in each panel) contain twelve unknowns, including the eight constants of integration K_1, K_2, K_3, K_4, G_1, G_2, G_3, and G_4; the load F; and the ordinates y_1, y_2, and y_3. Force F is included in the B-terms, and the ordinates are included in the C-terms, as may be noted in Eqs. 9. They can all be found by applying the following known conditions (the number after the dash in the last column indicates the value of a for the particular panel in question):

Condition No.	Statement of condition		Applies to Eq.:
I	When $x = 0$,	$y = e$	(8–1)
II	When $x = x_1$,	$y = y_1$	(8–1)
III	When $x = x_2$,	$y = y_2$	(8–2)
IV	When $x = x_3$,	$y = y_3$	(8–3)
V	When $x = h$,	$y = e + \Delta$	(8–4)
VI	When $x = h$,	$\frac{dy}{dx} = 0$	(10–4)
VII	When $x = x_1$,	$M_{(0-1)} = M_{(1-2)}$	(8–1) and (8–2)
VIII	When $x = x_2$,	$M_{(1-2)} = M_{(2-3)}$	(8–2) and (8–3)
IX	When $x = x_3$,	$M_{(3-4)} = M_{(2-3)} - R_s e_s + R_m e_m$	(8–3) and (8–4)
X	When $x = x_1$,	$\frac{dy}{dx}(0\text{–}1) = \frac{dy}{dx}(1\text{–}2)$	(10–1) and (10–2)
XI	When $x = x_2$,	$\frac{dy}{dx}(1\text{–}2) = \frac{dy}{dx}(2\text{–}3)$	(10–2) and (10–3)
XII	When $x = x_3$,	$\frac{dy}{dx}(2\text{–}3) = \frac{dy}{dx}(3\text{–}4)$	(10–3) and (10–4)

(It should be noted that Eq. 8 must be multiplied by the proper $E\,I$-values in order to obtain the bending moment when applying Conditions VII, VIII, and IX.)

The twelve equations obtained by applying these conditions may be solved to obtain the twelve unknowns.

Special Case I; Variable Moment of Inertia, Eccentricity at Tower Top, Tower Weight Considered, but Not Eccentric Roadway Loads.—Use the same procedure as for the "General" Case. Referring to Fig. 1, R_s and R_m now disappear and the problem reduces to that for a tower with three panels. There are nine unknowns: The six constants of integration K_1, K_2, K_3, G_1, G_2, and G_3; the load F; and the ordinates y_1 and y_2. They may all be found by applying nine known conditions which are identical with Conditions I to III, V to VIII, X, and XI of the "General" Case. (In any case that excludes eccentric roadway loads, a concentric load placed at the roadway level may be handled as if it were a tower weight concentration.)

Special Case II; Variable Moment of Inertia, Eccentricity at Tower Top, Tower Weight and Roadway Loads Not Considered.—Eqs. 9 are now greatly modified, inasmuch as R_s, R_m, and all values of W disappear. Since the shear is now continuous through the panel points, shears instead of slope may be equated at these points. The basic equations then become—

For moment:

$$\frac{d^2y}{dx^2} = -n_a^2\,y - B_a\,x = K_a \sin n_a\,x + G_a \cos n_a\,x \,\ldots\ldots\ldots (11)$$

for shear:

$$\frac{d^3y}{dx^3} = -n_a^2\frac{dy}{dx} - B_a = K_a\, n_a \cos n_a\, x - G_a\, n_a \sin n_a\, x \;\ldots\ldots (12)$$

The solution is obtained by finding the seven unknowns F, K_1, G_1, K_2, G_2, K_3, G_3. Four equations are obtained by equating moments and shears at the panel points. (Eqs. 11 and 12 must be multiplied by the proper $E\,I$-value to obtain moment and shear.) The other three equations are obtained by applying the following known conditions: In Eq. 11, for $a = 1$, $y = e$ when $x = 0$. In Eq. 11, for $a = 3$, $y = e + \Delta$ when $x = h$. In Eq. 12, for $a = 3$, $\frac{dy}{dx} = 0$ when $x = h$.

Special Case III; Variable Moment of Inertia, No Eccentricity at Tower Top, Tower Weight Considered, but Not Eccentric Roadway Loads.—This case is identical with Special Case I, except that $e = 0$.

Special Case IV; Variable Moment of Inertia, No Eccentricity at Tower Top, No Roadway Loads, and Tower Weight Neglected.—This case is identical with Special Case II, except that $e = 0$. In both cases, the labor required may be reduced somewhat by following the procedure outlined in a standard textbook.[5] The value of A is removed from the denominator of the first two terms of the general solution, Eq. 4, and incorporated in the constants K and G. By following through the development of the problem from this point, it may be seen that the resulting simultaneous equations which express equality of moments and shears at the panel points do not require the $E\,I$ coefficients.

Special Case V; Constant Moment of Inertia, Eccentricity at Tower Top, Tower Weight Considered, but No Eccentric Roadway Loads.—The equations required for solving this case are obtained from those of Special Case I by substituting the constant value of I for I_1, I_2, and I_3. Note that this substitution must also be made to obtain the values of n_1, n_2, and n_3. (It is obvious that the same substitution in the equations for the General Case will take the roadway loads into account.)

Special Case VI; Constant Moment of Inertia, Eccentricity at Tower Top, Tower Weight Neglected, No Roadway Loads.—Since the tower consists of only one panel, the problem reduces to the following two equations—

Moment:

$$E\,I\frac{d^2y}{dx^2} = -R\,y - F\,x = E\,I\,(K \sin n\,x + G \cos n\,x) \;\ldots\ldots (13)$$

shear:

$$E\,I\frac{d^3y}{dx^3} = -R\frac{dy}{dx} - F = E\,I\,(K\,n \cos n\,x - G\,n \sin n\,x) \;\ldots\ldots (14)$$

In Eq. 13, when $x = 0$, $y = e$:

$$-R\,e = E\,I\,G \;\ldots\ldots (15)$$

In Eq. 13, when $x = h$ and $y = e + \Delta$:

$$-R\,(e + \Delta) - F\,h = E\,I\,(K \sin n\,h + G \cos n\,h) \;\ldots\ldots (16)$$

In Eq. 14, when $x = h$ and $\frac{dy}{dx} = 0$:

$$-F = E\,I\,(K\,n \cos n\,h - G\,n \sin n\,h) \ldots\ldots\ldots\ldots (17)$$

Solving Eqs. 15, 16, and 17 for F:

$$F = \frac{R\,n\,[e\,(1 - \sec n\,h) + \Delta]}{\tan n\,h - n\,h} \ldots\ldots\ldots\ldots (18)$$

Special Case VII; Constant Moment of Inertia, No Eccentricity at Tower Top, Tower Weight Considered, No Eccentric Roadway Loads.—Equations may be found for this case by substituting the constant value of I in the equations found for Special Case III.

Special Case VIII; Constant Moment of Inertia, No Eccentricity at Tower Top, Tower Weight Neglected, No Roadway Loads.—This case is identical with Special Case VI when $e = 0$. Thus, Eq. 18 becomes:[6]

$$F = \frac{R\,n\,\Delta}{\tan n\,h - n\,h} \ldots\ldots\ldots\ldots (19)$$

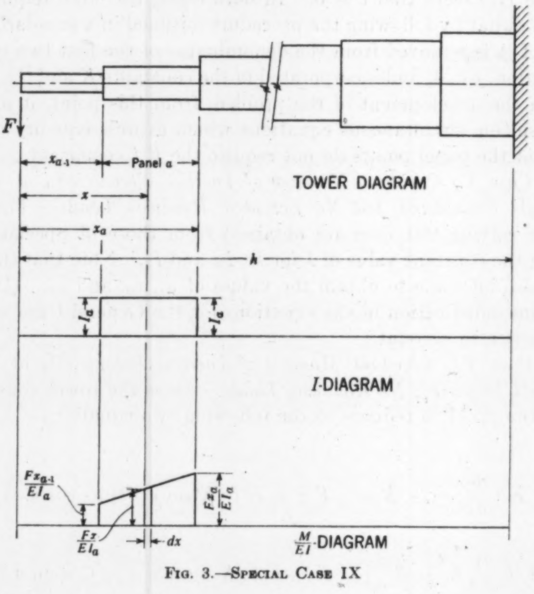

FIG. 3.—SPECIAL CASE IX

Special Case IX; Variable Moment of Inertia, Tower Weight Neglected, No Roadway Loads, and $R = 0$.—The problem (see Fig. 3) is now reduced to that of a simple cantilever of variable cross section. To find the deflection Δ by the moment-area method, find the moment of the $\frac{M}{E\,I}$-diagram about point 0. The moment of the small part of the diagram included in dx, in panel a, is: $dM_a = \frac{F\,x^2}{E\,I_a}\,dx$; integrating for panel a: $M_a = \frac{F}{E\,I_a}\int_{x_{a-1}}^{x_a} x^2\,dx$ $= \frac{F}{E\,I_a}\left(\frac{x_a{}^3 - x_{a-1}{}^3}{3}\right)$. Summing up for all panels:

---

[6] This case is also outlined in Pt. II of "Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, 10th Ed., pp. 278 and 279.

$$\Delta = \sum M = \frac{F}{E}\sum_0^h \frac{x_a{}^3 - x_{a-1}{}^3}{3\,I_a};$$

or

$$F = \frac{3\,\Delta\,E}{\displaystyle\sum_0^h \frac{x_a{}^3 - x_{a-1}{}^3}{I_a}} \quad \text{.....................(20)}$$

Special Case IX, Applied to the Condition in Which the Moment of Inertia Cannot Be Considered Constant Over Any Part of the Tower Leg.—If I can be expressed as a continuous function of x, the deflection may be found as the

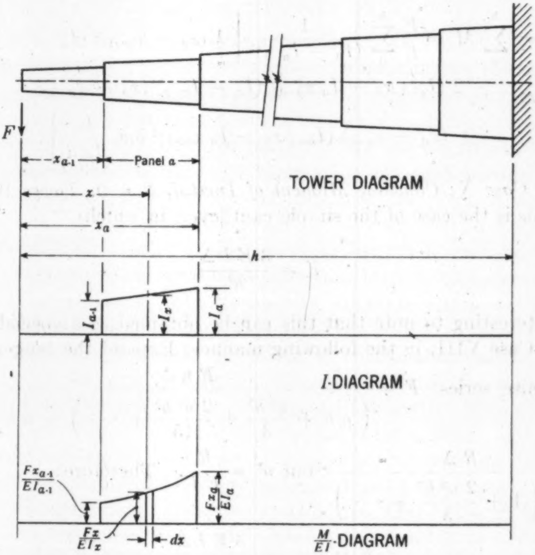

FIG. 4.—LAYOUT FOR FINDING Δ WHEN $R = 0$ AND I VARIES AS LINEAR FUNCTION OF x IN EACH PANEL

moment of the $\frac{M}{E\,I}$-diagram in the following manner:

$$\Delta = \int_0^h \frac{F\,x^2\,dx}{E\,I_x} = \frac{F}{E}\int_0^h \frac{x^2\,dx}{I_x} \quad \text{...............(21)}$$

More often the moment of inertia is not a continuous function of x, but can be expressed as a series of linear functions of x. From Fig. 4, the moment of the diagram for panel a is:

$$M = \frac{F}{E} \int_{x_{a-1}}^{x_a} \frac{x^2}{I_x}\, dx \qquad (22)$$

From Fig. 4, the equation of the I-diagram for panel a is:

$$\frac{I_x - I_{a-1}}{x - x_{a-1}} = \frac{I_a - I_{a-1}}{x_a - x_{a-1}} \qquad (23)$$

Solving Eq. 23 for I_x, substituting in Eq. 22 and integrating:

$$\begin{aligned} M = \frac{F}{E\,(I_a - I_{a-1})^3} \Big[& \tfrac{1}{2}\,(x_a - x_{a-1})^3\,(I_a{}^2 - I_{a-1}{}^2) \\ & - 2\,(I_{a-1}\,x_a - I_a\,x_{a-1})\,(I_a - I_{a-1})\,(x_a - x_{a-1})^2 \\ & + (x_a - x_{a-1})\,(I_{a-1}\,x_a - I_a\,x_{a-1})^2 \log_e \frac{I_a}{I_{a-1}} \Big] \qquad (24) \end{aligned}$$

Summing all segments:

$$\begin{aligned} \Delta = \sum_0^h M = \frac{F}{E} \sum_0^h \frac{1}{(I_a - I_{a-1})^3} \Big[& \tfrac{1}{2}\,(x_a - x_{a-1})^3\,(I_a{}^2 - I_{a-1}{}^2) \\ & - 2\,(I_{a-1}\,x_a - I_a\,x_{a-1})\,(I_a - I_{a-1})\,(x_a - x_{a-1})^2 \\ & + (x_a - x_{a-1})\,(I_{a-1}\,x_a - I_a\,x_{a-1})^2 \log_e \frac{I_a}{I_{a-1}} \Big] \qquad (25) \end{aligned}$$

Special Case X; Constant Moment of Inertia, $R = 0$, Tower Weights Neglected.—This is the case of the simple cantilever, in which

$$F = \frac{3\,E\,I\,\Delta}{h^3} \qquad (26)$$

It is interesting to note that this can be obtained as a special application of Special Case VIII, in the following manner: Expand the tangent in Eq. 19 as an infinite series: $F = \dfrac{R\,n\,\Delta}{\left(n\,h + \dfrac{n^3\,h^3}{3} + \dfrac{2\,n^5\,h^5}{15} + \cdots\right) - n\,h}$. Simplify: $F = \dfrac{R\,\Delta}{\dfrac{n^2\,h^3}{3}\left(1 + \dfrac{2\,n^2\,h^2}{5} + \cdots\right)}$; but $n^2 = \dfrac{R}{E\,I}$. Therefore:

$$F = \frac{3\,E\,I\,\Delta}{h^3\left(1 + \dfrac{2\,R\,h^2}{5\,E\,I} + \cdots\right)} \qquad (27)$$

Then, when $R = 0$, Eq. 27 becomes Eq. 26.

Special Case XI; Constant Moment of Inertia, Eccentricity at Tower Top, Tower Weight Neglected, $F = 0$.—In Eq. 18 of Special Case VI, let $F = 0$:

$$R = \frac{E\,I}{h^2}\left(\sec^{-1} \frac{e + \Delta}{e}\right)^2 \qquad (28)$$

Special Case XII; Constant Moment of Inertia, No Eccentricity at Tower Top, Tower Weight Neglected, No Roadway Loads, $F = 0$.—In Eq. 28, let $e = 0$. Then, since $\sec^{-1} \infty = \frac{\pi}{2}$:

$$R = \frac{E\, I\, \pi^2}{4\, h^2} \qquad (29)$$

Thus, in this case, the vertical load R is independent of the deflection Δ. This is Euler's formula for a column with fixed base and top free to move laterally. It yields the value of R for which the tower will be in unstable equilibrium. If, for any reason, the vertical load becomes slightly eccentric with respect to the center line of tower at its base, the tower will bend continuously until failure occurs.

For values of R greater than $\frac{E\, I\, \pi^2}{4\, h^2}$ or values of $n\, h$ greater than $\frac{\pi}{2}$ a negative F is required to hold the tower in equilibrium for any desired deflection. This may be verified by inspection of Eq. 19.

GENERAL OBSERVATIONS ON THEORY

Although not more than two changes in moment of inertia have been used in any case, and only four tower panels were used in the so-called "General Case," the same method may be applied for any number of changes in moment of inertia, and any number of tower panels. A more complex case simply increases the labor required. No matter what the conditions may be, this analysis requires two constants of integration for each section of tower in which there is no change in moment of inertia and no point at which a load is assumed to act. If the concentrated loads along the shaft are considered, the ordinate to each load point is another unknown that must be found. The remaining unknown is the horizontal tower-top load F. As soon as the setup of the problem is known, the number of simultaneous equations required may thus be determined by inspection.

If the effect of wind loads is desired in combination with any or all of the other loads, the wind can be considered as a series of concentrated horizontal loads acting at convenient points along the shaft. This will add to the complexity of the function of x in the expression for moment and may or may not introduce additional constants of integration, depending on whether or not the tower is thereby divided into a larger number of panels.

Since the lateral bracing of the tower adds somewhat to the effective moment of inertia, some designers find it advisable to add from 3% to 5% to the calculated moments of inertia of the tower leg to take account of this effect.

All of the simultaneous equations for solving any case are linear. Therefore, it is evident that, for a given value of R, F will be a linear function of Δ. For the same reason, the ordinate to any point on the elastic curve is a linear function of Δ.

As will be shown in the numerical examples, when R is plotted against F for a given Δ, the resulting curve is so nearly a straight line that it may be considered so for all practical purposes. This approximate linear relationship is demonstrated mathematically in the complete unabridged paper.[2]

These characteristics are a great aid in determining the flexure curve for a tower. For a given Δ, which may conveniently be taken as unity, the curve of applied vertical load plotted against F may be determined by finding only two points. Furthermore, for any given value of vertical load R along the curve, the F corresponding to a different Δ may be found by direct proportion if R is concentric. If R is eccentric, the value of F for various values of Δ may be found by a simple linear relationship only at the points where F has been calculated.

Numerical Applications

The results of a few numerical applications are given herein to support some of the foregoing general observations and to indicate the error to be expected if certain approximate short cuts are used. The dimensions and physical properties of the tower shafts are given in the unabridged paper.[2]

Tower A (Height = 188 Ft, One Change in Moment of Inertia, Equivalent I = 1,061.7 In²-Ft²).—The results for this tower are shown in Fig. 5(*a*), where values of F in terms of Δ are plotted against values of R. Curve 1 is based on Special Case III.

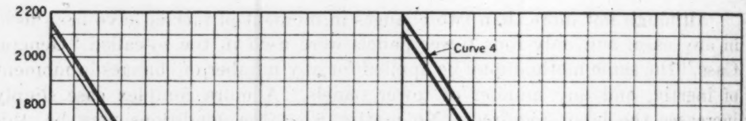

FIG. 5.—FLEXURE LINES

In finding curve 2, the weight of the tower was neglected. The F-intercept was found by using Special Case IX. The other two points were found by means of Special Case IV.

In finding curve 3, the weight of the tower was neglected and a constant moment of inertia was used. Curves that were established by finding more than two points indicated that, for all practical purposes, F is a linear function of R. This is also confirmed by the discussion in Appendix II of the unabridged paper.[2] For these reasons, only two points were found on curve 3. The F-intercept was found by using Special Case X, and the R-intercept by using Special Case XII. The constant I was found by equating the value of F on curve 2 for $R = 0$ to $\frac{3\,E\,I\,\Delta}{h^3}$. This equation was then solved for I to obtain an equivalent moment of inertia.

Tower B (Height = 188 Ft, Two Changes in Moment of Inertia, Equivalent $I = 1{,}078.2$ In²-Ft²).—The results for this tower are shown in Fig. 5(*b*). Curve 1 is based on Special Case III and curve 2 is based on a weightless tower. The F-intercept for curve 2 was found by using Special Case IX. The other three points were found by means of Special Case IV.

Curve 3 is also based on Special Case IV, but the following correction was applied to take account of the weight of the tower. For each of two of the points found on curve 2, the ordinates to the elastic curve were found at the points at which tower-weight loads were applied in finding curve 1. The tower-weight loads were then placed at these points. The sum of their moments about the center line of tower at the tower base, divided by the total height of tower, represents the approximate relief of F as found for curve 2, caused by the presence of the tower-weight loads.

Curve 4 is based on a weightless tower with constant I. The F-intercept was found by using Special Case X, and the R-intercept by using Special Case XII. The constant moment of inertia for this curve was found by equating the value of F on curve 2 for $R = 0$ to $\frac{3\,E\,I\,\Delta}{h^3}$. This equation was then solved for I to obtain an equivalent I.

Curve 5 is also based on a weightless tower with constant moment of a inertia equal to that used for curve 4. In this case, however, the vertical load R was given an eccentricity of 2 ft at the tower top, and all points were found for a tower-top deflection of 1 ft. Special Case XI was required to find the R-intercept, and Special Case VI to find the other points.

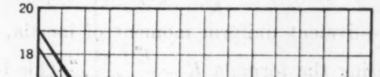

FIG. 6.—FLEXURE LINES FOR TOWER C

Tower C (Height = 702 Ft, Thirteen Changes in Moment of Inertia, Equivalent $I = 906{,}740$ In²-Ft²).—The results for this tower are shown in Fig. 6. In this case the ordinates represent values of F for a deflection of 1 in. Curve 1 is based on a weightless tower and required the use of Special Cases IV and IX.

Curve 2 is also based on Special Case IV, but the following correction was applied to take account of the effect of the tower weight. Using the tower elastic curve for the point on curve 1 where $R = 52{,}000{,}000$ lb, a reduction in F was found by the method used in finding the points of curve 3 for tower B. For the point where $R = 0$, the same numerical reduction in F was used.

Curve 3 is based on a weightless tower with a constant moment of inertia, and required the use of Special Cases VIII, X, and XII. The constant I was found by equating the value of F on curve 1 for $R = 0$ to $\frac{3\,E\,I\,\Delta}{h^3}$. This equation was solved for I to obtain an equivalent moment of inertia.

Discussion of Numerical Applications

The results of this numerical work clearly indicate that, as nearly as it can be plotted, the horizontal load required to produce a given deflection is a linear function of the vertical load. This is confirmed by the discussion in Appendix II of the unabridged paper,[2] wherein the deviation from a straight line is discovered algebraically. It appears that for many purposes of design and estimate, it would be sufficiently accurate to use the following method of obtaining the flexure characteristics of a tower:

Using Special Case IX, find F for the weightless tower when $R = 0$. Equate this value to $\frac{3\,E\,I\,\Delta}{h^3}$ (Special Case X) and solve for I. Using this as an equivalent uniform moment of inertia, find the value of R when $F = 0$ by using the formula $R = \frac{E\,I\,\pi^2}{4\,h^2}$. This is from Special Case XII, and is also Euler's formula. The line joining these two intercepts is a close approximation of the true flexure line for the weightless tower. The worst case arising in the foregoing numerical applications occurs for tower C. Curve 3 is found as in the foregoing, and curve 1 is the true flexure line for the weightless tower. In the vicinity of the dead-load tower-top reaction (52,000,000 lb), there is an error in F of 650 lb in 11,000 lb, or approximately 6%. This can be brought to within about 6% of the true value for the weighted tower by the following method: Divide the tower into convenient panels. Find the weight of each section and apply it at the proper panel point as a concentrated load. Find the ordinates to these points on the elastic curve of the weightless tower by using Special Case IX, or simply by assuming the tower to take the shape of some well-known curve such as the parabola. Find the sum of the moments of the weight loads about the center line of the tower at its base. Divide this by the total height of the tower and reduce all values of F found on the approximate line for the weightless tower by the amount of this quotient.

Finally, when it is desired to obtain the greatest accuracy which is possible without following the rigorous solution for the weighted tower, the following method may be used: Depending on whether or not the tower-top reaction is eccentric, use Special Cases II and IX, or Special Cases IV and IX, to find two points, the F-intercept and one other, on the flexure line for the weightless tower. For one of these conditions, find the ordinates to the elastic curve, and proceed as before to reduce F by taking moments of the tower weights about the tower base. The accuracy of this method for tower B may be seen by comparing curve 3, Fig. 5, which was found by this method, with curve 1, found by the exact method. It is doubtful, however, that this approximate method saves enough time, in comparison with the exact method, to make it worth while. In the exact method it is necessary to find only two points of the flexure line. It is the opinion of the writer that, if the degree of accuracy desired is such as to require the use of either the latter approximate method or the exact method, the exact method may as well be used unless the tower-weight concentrations cannot reasonably be placed at the points of change in moment of inertia. If they must be placed at intermediate points, additional integration constants will be required, and the last approximation described in the foregoing would be far less tedious than the rigorous solution.

All of this reasoning is based on the assumption that the principal objective of the solution is the deflecting force F required at the tower top. However, if the problem is to be solved in order to review the design of the tower shaft, and the principal objectives are the true elastic curve and the stresses in the tower sections, it appears to the writer that the only safe procedure is to use the rigorous solution.

In some design or erection problems, it may be desirable to set down a series of flexure lines for various values of deflection or eccentricity. The general disposition of various sets of curves for a few simplified cases is shown in Fig. 7. The following methods of attack are suggested by the arrangement of these lines.

(*a*) SPECIAL CASES VI, X, AND XI' (*b*) SPECIAL CASES VIII, X, AND XII (*c*) SPECIAL CASES VI, X, AND XI

FIG. 7.—ARRANGEMENT OF FLEXURE LINES FOR VARIOUS CASES

Special Cases VI, X, and XI.—In Fig. 7(*a*), $e > 0$ = constant, and each curve represents one value of Δ. The procedure is to find the F-intercept and one other value of F in terms of Δ. Any desired number of lines may then be found by applying various values of Δ to these expressions.

Special Cases VIII, X, and XII.—In Fig. 7(*b*), $e = 0$, and each curve represents one value of Δ. The procedure is the same as in Fig. 7(*a*) to find the F-intercept for each line. For the simple case of a constant moment of inertia and a weightless tower, the common R-intercept is found by Special Case XII. For other cases: Find a point on one line; produce this line from its F-intercept through the point just found to the R-axis; and draw all other lines through this common R-intercept.

Special Cases VI, X, and XI.—In Fig. 7(*c*), $e > 0$; Δ = constant; and each curve represents one value of e. The procedure is to find the common F-intercept and solve for one other point on each line.

CONCLUSION

The relation between horizontal and vertical tower-top loads for any tower-top deflection can be found by rigorous mathematical analysis, which includes the effects of the following influences:

(1) An eccentricity of the vertical tower-top load;

(2) The eccentricity of the weight of the tower (considered as a series of concentrated loads) caused by deflection;

(3) Reactions at the roadway level; and

(4) Wind loads (considered as a series of concentrated horizontal loads).

The analyses of this case and of several simpler cases have been developed in this paper. Many of the latter have been published elsewhere, but the writer feels that there is a definite advantage in having all these cases assembled for ready reference.

It is possible to obtain approximate values which are very close to the true values by means of short-cut methods, several of which are described herein.

It is mathematically correct to state that, for any given combination of other loads, the horizontal tower-top load is a linear function of the tower-top deflection. For all practical purposes, it is correct to state that, for a given deflection, the horizontal tower-top load is a linear function of the vertical tower-top load.

ACKNOWLEDGMENT

The writer wishes to acknowledge with gratitude the inspiration of the late George E. Beggs, M. Am. Soc. C. E., and his generous aid in the form of constructive criticism and advice. He also wishes to express his appreciation to the John A. Roebling's Sons Company for free access to its files and the use of its facilities, and in particular to Walter F. Weber, wire rope engineer of that firm, for his active help and useful advice; to Professors H. P. Robertson of Princeton University, Princeton, N. J., and M. S. Knebelman of Washington State College, Pullman, Wash., for their helpful advice in developing the mathematical theory which is included in the paper and the appendixes of the unabridged paper.[2]

DISCUSSION

Francis P. Witmer,[7] **M. Am. Soc. C. E.**—A complete method for analyzing the stresses in a suspension bridge tower under a variety of imposed conditions is presented in this paper. It is particularly interesting that the author has based his development upon one of the almost forgotten members[3] of the series that were classics in their field fifty years ago. It is unfortunate that the more detailed study upon which this paper was based[2] could not have been presented in full. The derivation of Eq. 4 would then have been clear to one who happens not to be acquainted with Professor Robinson's valuable little treatise published in 1882, and who is not in a position readily to consult the complete paper in the Engineering Societies Library in New York City.

For the usual case of a tower without eccentricity at the top and with a variable moment of inertia, the writer has had satisfactory results by using Eq. 19 of Case VIII, first determining an equivalent moment of inertia I by equating Δ in Eq. 20 of Case IX to the deflection for a cantilever with constant moment of inertia, $\Delta = \frac{F\,h^3}{3\,E\,I}$. The value of I, so found, may then be used in the quantity $n = \sqrt{\frac{R}{E\,I}}$ without serious error. The author has applied a similar procedure to several numerical cases with results that seem to justify this conclusion, particularly when it is remembered that the fiber stress in the tower due to bending is generally small in comparison with the direct unit stress. Incidentally, Eq. 19 may be readily derived by the writer's method, which is cited in the paper.[4]

John I. Copp,[8] **Assoc. M. Am. Soc. C. E.**—The procedure for the exact solution of tower stresses for all loading conditions that ordinarily occur in a plane parallel to the bridge axis is described in this paper. The author has also indicated some approximations that may be used with accuracy for certain loading conditions in evaluating the tower stresses and deflections. His proposed method of finding the effect of the tower dead load on the horizontal force F at the tower top by "* * * assuming the tower to take the shape of some well-known curve such as the parabola" (see heading "Discussion of Numerical Applications") has been used by the writer and found to give a very close approximation to the true value.

When preliminary investigations are being made for planning cable-spinning operations or tower erection, it is of value to have some rapid means of approximating the tower deflections and stresses prior to the final analysis by the exact method. By applying the foregoing parabolic assumption, it is comparatively simple to derive the approximate equations for any and all loading conditions that are indicated by the author in his various cases. The assumption of a parabolic curve for the tower eliminates the solution of all differential equations and the determination of the constants of integration when deriving the equations.

---

[7] Director, Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.

[8] Designer, Bethlehem Steel Co., Fabricated Steel Constr., Bethlehem, Pa.

The writer believes that as a supplement to the author's formal solution of the various cases the method of deriving the approximate equations would be of value. The derivation of the equations for a few typical loading conditions is given herein with some numerical applications by the exact and approximate methods for comparison.

In the derivation of the approximate equations the author's notation will be used in so far as it is applicable with additions as required:

h = tower height, in feet;

Δ' = initial tower-top deflection for a free standing tower, in feet;

Δ = final tower-top deflection, in feet;

δ_n = deflection increment of tower top (caused by tower moments that are functions of the tower curve), in feet;

$\Sigma\delta$ = total tower-top deflection (caused by tower moments that are functions of the tower curve), in feet;

R = known vertical load at tower top, in pounds;

F_Δ = horizontal force at tower top to maintain a known horizontal deflection Δ, in pounds;

F = a horizontal force at tower top, in pounds;

E = modulus of elasticity for the tower, in pounds per square inch;

e = eccentricity of the vertical load R with respect to the center line at tower top, in feet;

M_x = bending moment in tower at a distance x from the tower top, in foot-pounds; and

w = dead load of tower per linear foot of height (assumed uniform).

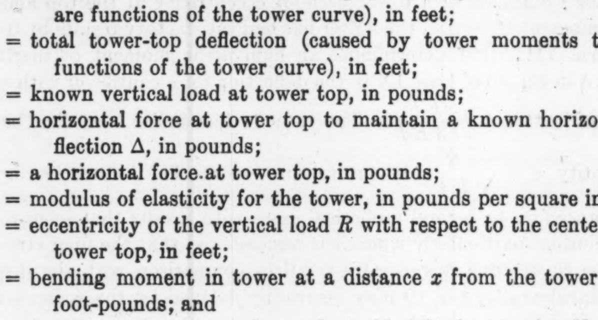

FIG. 8

Free Standing Tower (Total Deflection of Tower Top Due to the Dead Load of Tower).—Assume the tower curve $T\ A\ B$ (Fig. 8(a)) to be a parabola with its vertex at point B and with an initial deflection Δ' (Fig. 8(*b*)) resulting from any tower moments that are not functions of the tower curve.

The total deflection $\Sigma\delta$ (Fig. 8(*b*)) due to the dead load of the tower is determined by taking the sum of a geometrical series, since the deflection δ' will induce an additional deflection δ'' and an infinite number of deflection increments will result with a constant ratio between successive increments—that is, $\frac{\delta'}{\Delta'} = \frac{\delta''}{\delta'} =$ etc. The first term of this series, δ', is determined by taking moments of the $\frac{M}{E\,I}$-diagram, for the tower dead load, about the tower top.

The formula for the sum of a geometrical series is

$$s = \frac{a\,(r^n - 1)}{r - 1} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

which, applied to the tower deflection increments, gives $a =$ first term $= \delta'$; $r =$ ratio for the series $= \frac{\delta'}{\Delta'}$; $n =$ number of terms $= \infty$; $s =$ sum of the series $= \Sigma\delta$; and the sum of the series then will be

$$\Sigma\delta = \frac{\delta'\left[\left(\frac{\delta'}{\Delta'}\right)^{\infty} - 1\right]}{\frac{\delta'}{\Delta'} - 1} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

In Eq. 31 the ratio $\frac{\delta'}{\Delta'}$ must be less than unity (if the critical loading for the tower has not been reached); hence

$$\lim_{n \doteq \infty}\left(\frac{\delta'}{\Delta'}\right)^n = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

and the equation for deflection will be

$$\Sigma\delta = \Delta'\left(\frac{\delta'}{\Delta' - \delta'}\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

In Eq. 33 the value of δ' is equal to the moment of the $\frac{M}{E\,I}$-diagram, about the tower top—

$$\delta' = \int_{x=0}^{x=h} \frac{M_x\,x}{E\,I}\,dx \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

in which the value of M_x, the moment at the point x, due to the dead load of the tower above point x, for a parabolic curve, can be shown to be

$$M_x = \frac{\Delta'\,w}{h}\,x^2 - \frac{2}{3}\,\frac{\Delta'\,w}{h^2}\,x^3 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Substituting this value of M_x in Eq. 34 and evaluating the integral—

$$\delta' = \frac{1}{E\,I}\int_{x=0}^{x=h}\left(\frac{\Delta'\,w}{h}\,x^2 - \frac{2}{3}\,\frac{\Delta'\,w}{h^2}\,x^3\right) x\,dx = \Delta'\left(\frac{7\,w\,h^3}{60\,E\,I}\right) \ldots (36)$$

The deflection for the free standing tower due to its own dead load is then found by substituting the value of δ' from Eq. 36 in Eq. 33

$$\Sigma\delta = \Delta'\left(\frac{7\,w\,h^3}{60\,E\,I - 7\,w\,h^3}\right) \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

The value of Δ (Fig. 8(*b*)) then will be

$$\Delta = \Delta'\left(1 + \frac{7\,w\,h^3}{60\,E\,I - 7\,w\,h^3}\right) \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Tower with Controlled Deflection.—When the tower-top deflection is controlled by a known amount Δ', as in cable-spinning operations, the reduction in the horizontal force F (say F') due to the dead load is found by equating the deflection caused by a single horizontal force F' to the deflection δ' and solving for F'; that is,

$$\frac{F'\,h^3}{3\,E\,I} = \Delta'\left(\frac{7\,w\,h^3}{60\,E\,I}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

and

$$F' = \Delta'\left(\frac{7}{20}\,w\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Applying this reduction, F', to a tower with a controlled deflection Δ', the horizontal force F is determined by deducting, from the force required to deflect the weightless tower, an amount Δ', the force F'.

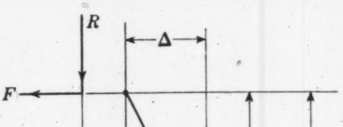

FIG. 9

The force required to deflect the weightless tower an amount Δ' is

$$F_\Delta = \frac{\Delta'\,3\,E\,I}{h^3} \ldots\ldots\ldots (41)$$

Hence, the net force will be

$$F = \frac{\Delta'\,3\,E\,I}{h^3} - \Delta'\,\frac{7}{20}\,w \ldots . (42)$$

in which, as previously stated, Δ' is an initial deflection of the tower top resulting from moments that are not functions of the tower curve.

Free Standing Tower with Horizontal and Eccentric Vertical Loads at Tower Top.—In Fig. 9 the moment at any point x, y will be

$$M_x = F\,x + R\,(e + y) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

which may be considered as the sum of three moments, $F x$, $R e$, and $R y$. The moments $F x$ and $R e$ are independent of the tower curve, whereas the moment $R y$ is a function of the tower curve. The deflection resulting from the moment $R y$ must be treated as the sum of a geometrical series, for a free standing tower, as was done in the case for the dead load of the tower. The deflection due to the horizontal force F will be

$$\Delta_F = \frac{F h^3}{3 E I} \quad \text{(44a)}$$

The deflection due to the moment $R e$ will be

$$\Delta_{Re} = \int_{x=0}^{x=h} \frac{R e x}{E I} dx = \frac{R e h^2}{2 E I} \quad \text{(44b)}$$

The tower-top deflection due to these two moments then will be

$$\Delta' = (\Delta_F + \Delta_{Re}) = \frac{F h^3}{3 E I} + \frac{R e h^2}{2 E I} \quad \text{(45)}$$

which is the initial deflection for determining the deflection caused by the moment $R y$.

The deflection due to the moment $R y$ is determined by the moment of the $\frac{M}{E I}$-diagram about the tower top:

$$\delta' = \int_{x=0}^{x=h} \frac{R y x}{E I} dx \quad \text{(46)}$$

in which

$$y = \frac{\Delta'}{h^2}(2 h x - x^2) \quad \text{(47)}$$

Then:

$$\delta' = \int_{x=0}^{x=h} \frac{R \Delta'}{E I h^2}(2 h x - x^2) x \, dx = \Delta' \frac{5 R h^2}{12 E I} \quad \text{(48)}$$

The total deflection due to the moment $R y$ will be equal to the sum of a geometrical series with an infinite number of terms as indicated by Eq. 33. Substituting for Δ' and δ' their values as given by Eqs. 45 and 48, respectively, in the general Eq. 33, and adding the initial deflection Δ':

$$\Delta = \left(\frac{F h^3}{3 E I} + \frac{R e h^2}{2 E I}\right)\left(1 + \frac{5 R h^2}{12 E I - 5 R h^2}\right) \quad \text{(49)}$$

which is the total deflection for a free standing tower with a horizontal and eccentric vertical load at the tower top.

For a free standing tower with a horizontal force F and a concentric vertical load R, the value of e in Eq. 49 becomes zero and the equation for deflection will be

$$\Delta = \frac{F\,h^3}{3\,E\,I}\left(1 + \frac{5\,R\,h^2}{12\,E\,I - 5\,R\,h^2}\right) \dots\dots\dots\dots (50)$$

It is of interest to note that an approximate value of the critical concentric load R, for a free standing tower, may be evaluated from the general Eq. 31. It can be shown that Eq. 31 approaches infinity as the ratio $\frac{\delta'}{\Delta'}$ approaches unity. Equating the ratio in Eq. 48 to unity and solving for R,

$$R = \frac{12\,E\,I}{5\,h^2} \dots\dots\dots\dots (51)$$

A comparison of this approximate critical load with Euler's theoretical load shows an error of less than 3% in the approximate value.

When the tower is loaded at the top with an eccentric vertical load and with the horizontal deflection controlled, the horizontal force for equilibrium is determined by equating (for a weightless tower) the deflection resulting from a horizontal force F' to the sum of the first increments of deflection caused by the moments $R\,e$ and the vertical load R and solving for F':

$$\frac{F'\,h^3}{3\,E\,I} = \frac{R\,e\,h^2}{2\,E\,I} + \Delta'\,\frac{5\,R\,h^2}{12\,E\,I} \dots\dots\dots\dots (52)$$

or,

$$F' = \frac{3}{2}\,\frac{R\,e}{h} + \Delta'\,\frac{5\,R}{4\,h} \dots\dots\dots\dots (53)$$

which gives the reduction in the horizontal force required to deflect the tower an amount Δ' with no other loads. The reduced force F resulting from the eccentric vertical load will then be

$$F = \frac{3\,\Delta'\,E\,I}{h^3} - \frac{3}{2}\,\frac{R\,e}{h} - \Delta'\,\frac{5\,R}{4\,h} \dots\dots\dots\dots (54)$$

In Eq. 53 the value of e may be either negative or positive, depending on whether the moment $R\,e$ decreases or increases, respectively, the moment $F\,x$ at any point in the tower. The value of e will be zero for a concentric load R. When R is concentric, the resulting horizontal force F will be

$$F = \Delta'\,\frac{3\,E\,I}{h^3} - \Delta'\,\frac{5\,R}{4\,h} \dots\dots\dots\dots (55)$$

Numerical Applications of the Approximate Solutions.—Refer to curve 3, Fig. 5(*a*) of the paper, as a comparable example and apply the corresponding approximate Eq. 55 with the following values: R (assumed) = 1,200,000 lb; h = 188 ft; I = 1,061.7 in^2 ft^2; Δ' (assumed) = 1.0 ft; E (assumed) = 29,000,000 lb per sq in.; and F = 5,922 lb.

Entering Fig. 5(*a*) with R = 1,200,000 lb, the value of $\frac{F}{1{,}000\,\Delta} = 6$, which gives a value of F = 6,000 lb and shows an error, in the approximate solution, of about 1.5% when compared to the author's comparable case.

Using the same tower properties and assuming it as free standing, the total deflection by the approximate solution (Eq. 50) is $\Delta = 1.013$ ft, in which R, E, I, and h are as stated previously and F (from Fig. 5(a)) is 6,000 lb. From curve 3, Fig. 5(a): $\Delta = \frac{F}{6{,}000} = 1.00$ ft, which shows an error of about 1.5% in the approximate solution.

It appears from the foregoing derivations and numerical examples that the approximate solutions may be used to advantage as an approach to the formal solutions as outlined by the author. They also might be used for the preliminary design of towers or as the first approximation if the tower stresses were to be determined by successive approximations.

BLAIR BIRDSALL,[9] ASSOC. M. AM. SOC. C. E.—The writer appreciates the discussion presented by Professor Witmer. The reference in the paper to Professor Robinson's booklet[3] was intended purely as an historical note.

To obtain the derivation of the general solution (Eq. 4) of the differential Eq. 3, it is not necessary to refer to Professor Robinson's booklet or to the writer's complete paper which is on file in the Engineering Societies Library in New York City. This solution may be obtained by applying the procedure recommended in textbooks on differential equations for linear differential equations with constant coefficients.

Mr. Copp has presented an interesting method of obtaining closely approximate results without the use of trigonometric functions. For this reason, many engineers may find Eq. 54 a more handy tool than Eq. 18 for finding approximate results under Special Case VI. This may also be true of a combination of Eqs. 42 and 54 or Eqs. 42 and 55 when the effect of tower weight is considered. However, the writer believes that if tower weight is to be considered at all, it should be handled as a series of voussoirs of weight increasing from top to bottom of tower.

The writer does not believe that, for a weightless tower with uniform moment of inertia, Eq. 55 has any advantage in ease of application over Eq. 26 (Special Case X) and Eq. 29 (Special Case XII), which were used to obtain curve 3 of Fig. 5(a). Since Eqs. 26 and 29 are statements of its two intercepts, the equation of curve 3 is—

$$F = \frac{3\,E\,I\,\Delta}{h^3} - \frac{12\,\Delta\,R}{\pi^2\,h} \quad \text{.................... (56)}$$

The similarity of Eqs. 55 and 56 and the fact that they are equally easy to apply may be seen at a glance. They are both based on the assumption that F is a linear function of R, and both assume a weightless tower and a constant moment of inertia. However, both intercepts of Eq. 56 are true values for this type of tower, whereas that is true of only the F-intercept of Eq. 55. For that reason, the writer is inclined to favor Eq. 56.

In his numerical application, Mr. Copp has compared a value of F (5,922 lb) computed from Eq. 55 with a corresponding value (6,000 lb) taken from a graph of Eq. 56. It appears to the writer that, for a true comparison, computed values should be used in both cases. The corresponding computed value of F from Eq. 56 is 6,140 lb. When this is compared with 5,922 lb, the resultant discrepancy is 3.6%. This is a small error but one that can be avoided without increase in labor.

As stated in the "Introduction," one of the writer's principle aims in presenting the paper was to make available to the profession certain handy tools for the closely approximate solution of an otherwise tedious problem. Mr. Copp's discussion is a valuable addition to this "tool kit."

Paper No. 2149

EVALUATION OF FLOOD LOSSES AND BENEFITS

By Edgar E. Foster,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. L. Chandler, E. F. Chandler, Charles B. Burdick, H. K. Barrows, Roger E. Amidon, Hyman J. Fine, Otto F. Buzhardt, Malcolm Elliott, John B. McAleer and John B. Drisko, and Edgar E. Foster.

Synopsis

The analysis of the damages, including the annual flood loss, constitutes the outstanding problem of the economics of flood control in which benefits must be weighed against costs. It is the purpose of this paper to present some methods that have been used by the writer in the U. S. Engineer Department. The primary condition imposed is that the method must be based on sound principles of mathematics, hydrology, and economics. In order to demonstrate that this condition was met, the paper contains a brief description of the various types of damage, some fundamental concepts of economics, a discussion of frequency and damage curves, and an example of the computation of the annual loss.

Introduction

Economic studies form an essential part of the investigation of practically every constructive enterprise, and works for flood control or flood protection are no exception, particularly when the loss of human life is not a factor, Indeed, lacking (as they usually do) any direct esthetic or intellectual appeal, their justification must be made primarily upon an economic basis. Although it is true that in great catastrophic floods the loss of life is appalling and the prevention of this loss is also a justification, nevertheless the costs of flood control are necessarily measured in economic terms and, to make adequate comparison of cost against benefit, the latter must be gaged on the same basis. Moreover, aside from the loss of life, flood control or protection is entirely an economic matter.

The losses from which the benefits are computed may be found by investigation or appraisal, and the costs can be estimated in the same manner as

---

Note.—Published in May, 1941, *Proceedings*.

[1] Head, Flood Control Section, U. S. Engr. Office, Omaha, Nebr.

costs of other structures. When the losses are known, the annual benefits can be computed and compared with annual costs. This is the object of the economic study. On this comparison depends: (1) Whether or not any protective measures are justified; (2) to what extent protection may be given; and (3) in part, what kind of works may be provided.

The analysis of flood losses and computation of annual loss must proceed on a rational basis as far as such bases can be found in the relevant fields of economics, mathematics, and hydrology. It is the purpose of this paper to develop some methods applicable to such analysis.

DESCRIPTION OF FLOOD DAMAGE

Flood losses arise from the occupation of the fluvial plains that are sufficiently high to escape the frequent and smaller freshets but are still low enough to be inundated by the greater and rarer floods. From the beginning of civilization, the flood plains have been favored lands for settlement. Prior to the development of modern railways, rivers formed the most important means of commercial transportation and commerce, which required a settlement where navigation could be had if such a site were at all possible. This factor is probably the most potent of all that promoted riverside settlement and, moreover, is a world-wide factor in city growth. Another reason for such settlement is the ease of construction on the flat terrane. This means cheaper construction for other and more modern forms of transportation, as railways and highways. In some cases, notably in New England, the existence of potential water power induced the development of industries on the banks of rivers. Then, regardless of the original reason for settlement, once a city is established on a flood plain, it will stay. People are so loath to leave their property that only the worst catastrophes will force them to leave any except the smallest towns. Therefore, as long as cities and towns occupy flood plains, and as long as rivers have floods, there will be flood losses from which protection will be sought.

The diversity of losses is as great as the economic interests of society itself, since floods inundate everything on the plain as, perhaps, may be the right of floods. However, since society has found the land of flood plains most desirable for nearly every human purpose, it will continue to occupy that land and consequently continue to suffer losses in every line of activity. Industrial, commercial, utility, municipal, recreational, social, and agricultural interests all pay toll for trespassing on a flood plain, and others, throughout the present-day closely knit social and economic organization, contribute in a diminishing degree, although far from the scene of disaster.

Industrial losses include those sustained by establishments engaged in manufacturing activities in which raw materials are processed to form a finished product for use by a consumer or in another manufactory. Usually the structures used for manufacturing purposes are sufficiently strong to withstand the onslaught of a flood and will survive unless they are located so close to the riverbank that they become undermined. Small auxiliary buildings may be washed away or wrecked by other means. Wooden floors will swell and bulge so that extensive repairs or replacements are required. Floor covering and wall finishing will be damaged and windows will be broken.

Machinery is injured to a varying degree that depends upon the type of machine. Engines and pumps and similar heavy machines will not suffer any great damage from simple immersion but will require dismantling and thorough cleansing. Electrical machinery, particularly motors and generators, requires thorough cleansing and even more thorough and careful drying. Even then, such machinery is subject to rapid deterioration and early replacement. The more fragile machinery, such as is used in the textile industry, is subject to breakage by floating debris as well as the foregoing damage. Many classes of raw materials and finished products, such as textiles and clothing, are liable to total destruction. Others (some heavy rubber goods, for example) may be reclaimed by thorough cleaning. Still others may be damaged in quality so that their value is reduced. Some industries (rayon, for example) that operate in a continuous process suffer a loss simply because of the untimely interruption which necessitates clearing the plant of material in process.

Industrial losses also arise from the destruction or damage to records if the administrative offices are so located that they too are flooded. Some papers may be recovered by careful drying but others may be a total loss. A case of the latter kind occurred in the Merrimack River Valley in the flood of March, 1936. The owner of a chemical manufacturing plant had some chemical formulas that had been obtained after several years of study and experimentation. The formulas, having been written out and left in the office, were completely destroyed by the flood and could be reproduced only by repeating the investigations at a heavy cost. Furthermore, all factories suffer heavy indirect losses because of the interruption of the usual business with a continuation of fixed costs. This loss may be incurred whether or not the plants are located in the flood zone, but, of course, not to the same extent.

Under commercial losses may be included all those sustained by establishments engaged in trade, wholesale and retail; banks and other financial institutions; professional and other offices; service concerns such as laundries, plumbers, barbers, beauty shops, restaurants and hotels, theaters, and similar lines of business that are too numerous and diversified to list in detail.

Retail and wholesale shops lose heavily in merchandise that has been submerged. Goods that have been soaked by dirty and polluted flood water are usually a total loss, although there may be some kinds that may be reclaimed to sell at much reduced prices. Damage to accounts and records results in a loss, the minimum value of which is the cost of restoring them by cleansing and drying into some recognizable condition. Buildings and fixtures are always damaged at least to the extent of requiring cleaning and redecorating. Plate-glass fronts, which are a conspicuous feature of retail shops, are heavy sufferers if the flood rises high enough to carry debris against them. Likewise, all affected concerns sustain an indirect loss because of suspension of business.

Under the term "utilities" may be grouped all agencies or private and public organizations that provide or sell some form of service to the consumer or patron. These agencies include electric, gas, telephone and telegraph, and railroad companies, and water works, among private organizations; under public ownership may be included water works, sewerage systems, and streets and highways.

Since utilities deal in service rather than goods, there is relatively little to be lost in stocks of goods, either in raw materials or finished products of their principal business. Gas companies, however, may lose gas from their containers or pipe lines, and both gas and electric utilities may suffer damage to merchandise which is sold for the utilization of their services. Both also may lose stocks of operating supplies, and both may sustain losses in business due to the inundation of their patrons and the suspension of other business. Hydroelectric power houses and dams and river crossings of pipe lines and transmission lines are danger points and frequently are damaged severely.

Railroads and highways suffer because grades are damaged by slides or are washed out entirely, taking pavements or rails with them as the case may be. Railroads sustain damage to rolling stock, which is lost not infrequently when freight cars are loaded with rock or other ballast and placed on bridges that are in danger of going out. Both railroads and highways suffer loss of bridges. In many cases the entire bridge is destroyed; in others, the piers may be damaged or the approaches eroded. Occasionally the bridge superstructure may be damaged, although left in place. The submergence of both highways and railways causes a temporary rerouting of traffic with consequent greater cost to the public in the case of the former and to the railway company in the latter case.

Dams, like bridges and all other structures in rivers, are particularly vulnerable to floods. Flashboards may be washed away by any freshet, gates may be damaged, or the abutments washed out by heavy and high water; or the entire dam may fail and release the water in storage to augment the flood below. Because a dam has successfully passed one flood is no reason to be certain that it will pass all others. All structures in the channels are subject to damage and may be weakened by successive floods until one finally washes them out.

Under the term "municipal" losses may be grouped all damage to property and all increased cost of municipal operation during the flood: These include all losses sustained by city, county, state, or other governmental agencies, including the federal government.

Streets and roads suffer heavy damage in flood from washing and erosion, and heavy deposits of debris must be removed after the water has subsided. Sewer outlets in streams and water-main crossings are subject to damage. Municipal buildings are liable to the same kind of damage as other structures, because floods are no respecters of authority. In addition to the physical loss, the government must spend large sums of money for relief of those who are driven from their homes. The police duties are increased by the emergency, and frequently other forces are required to maintain civic order, the cost of which is a true flood loss.

Farm and rural losses include all damage sustained by agricultural lands and forests, together with all appurtenant improvements. This includes the loss of livestock that may be trapped and drowned; damage or destruction of buildings and farm equipment; loss of crops that may be in the field, growing or harvested; and loss due to prevention of planting, erosion of valuable land, or deposits of debris that may render the soil untillable. The flood may wash out fertilizer that has been placed on the land in preparation for crop, or it may necessitate repeating the work of preparing the field for planting. It may erode the topsoil so that replacement may be necessary or one or more years of fruitless cultivation may be required to restore the fertility.

Residential losses include all damage to dwellings, both the buildings and the grounds, and the furnishings and other personal property commonly used or kept around homes. As in other types of damage, the extent varies greatly as the desires and means of the occupant vary. Entire houses may be carried away if they are located in areas submerged by swift, deep water or they may be undermined by erosion of the banks of the stream. Buildings, household goods, and generally the land may be charged off as a total loss in cases where the entire house is taken away. In other cases the personal property is damaged by immersion; furniture and other household furnishings are badly damaged and many pieces (pianos, for example) must be replaced. The dwelling must be thoroughly cleansed and redecorated and may require more or less extensive repair work. Moreover, there is usually some cost of moving out because of rising water and providing other habitation for the duration of the flood. This cost is properly chargeable to flood losses.

The term "social losses" may apply to all losses arising from the interruption of normal, individual, or collective social activity and to the personal risk of life and health endangered by floods. The term is necessarily rather vague and very broad. The losses are indefinite in most cases and may be practically nothing, or they may be large. For example, an interruption of an afternoon bridge game is an inconvenience but the loss caused by such an interruption is negligible or nonexistent. On the other hand, the personal risk may be very real. The inundation may result in sickness and death, a loss that cannot be measured in terms of money. These social losses may be considered as indirect losses accompanying the direct residential damage.

SOME DEFINITIONS OF WEALTH AND VALUE

The considerations of flood damages and benefits involve the most basic and fundamental concepts of the science of economics. It is desirable to define these concepts herein before proceeding to the analysis of losses.

The first concept is that of wealth. It is necessary to know what can be classed logically as the real wealth of a community that has suffered flood damage in order to determine the true loss. By the term "wealth" is meant the sum of all goods, fixed or movable, which have value to individuals or organizations of individuals who have a commonly recognized title to ownership of the goods or property in question. Wealth may be owned by private or public agencies. "Wealth can be described by means of a stock-taking or inventory, but it can be summed or measured as a whole only in terms of its money value. * * * Its value is the sum of the values of existing property rights."[1]

Economic goods may be divided into two general classes—productive and consumptive goods. These two classes include all forms of property that constitute the real wealth of the community or the country. They include both real and personal property. They do not, however, include evidences of indebtedness, such as bonds, because such papers are essentially claims to other property, the title of which rests in other owners.

---

[1] "Wealth," *The Encyclopædia Britannica*, 14th Ed., Vol. 23, p. 448.

Productive property is taken to be that which is devoted to the use of producing other goods or service in commercial operations. It includes both real and personal property—that is, land and improvements and all equipment devoted to such production. It consists of the property used in all commerce, industry, utilities, and agriculture; it is fundamentally all property used to produce an income.

Consumptive or nonproductive property, on the other hand, includes all property, both real and personal, put to uses that do not produce other goods or commercial services. Nonproductive fixed property is essentially a kind of "consumptive good" because it is used directly by the consumer or patron. Its utility is obtained directly by the user. Nonproductive property includes residences, religious and educational institutions (both the land and buildings), libraries and art galleries, parks and similar recreational areas for which admission is not charged, streets, highways, sewers (generally), and governmental and municipal structures. This differentiation between productive and consumptive property is essential to the proper comprehension of the effect of flood losses on depreciation.

Another concept for which a definition must be made is value. For the purposes of this paper, two definitions are given, interrelated but viewing the concept differently. First, the value of any particular item of property may be defined or measured as the quantity of other goods that may be given or received in exchange; under existing economic conditions the "other goods" is nearly always money. The value arrived at will depend upon two or more parties involved in a transaction. This is the exchange or objective value and is the definition usually in mind when the worth of goods is discussed.

In contrast with the exchange value is the subjective value, which is the worth of an item of property in the consideration of the holder in comparison with other goods. This value depends upon an individual's sentiments and preferences, without effective regard to the utility of the property in question. It cannot be measured directly in money since the holder usually places a greater consideration on the property than its utility to others is worth.

Actually, the subjective value enters the appraisal of a personal need and the purchase of every article of consumptive goods obtained for the usefulness to the purchaser. The particular item that is bought will be what the buyer believes will give him greater utility than some other "good" that may be had for the same money. This displacement value of consumptive goods is entirely subjective, but in the case of production goods it will depend upon the relative costs of production attainable and may be measured or estimated in terms of money. An item, therefore, is worth to the consumer what he will pay for it and to the producer what he can earn with it.

If the item of property is offered for sale at a price within the replacement value, the objective or exchange value is reached. On the other hand, if the individual refuses to pay the exchange price or cost, it should be safely inferred that the subjective value is not worth to him as much as is asked. Questions of indirect losses, business losses, depreciation of property, risk of health and life, and evaluation of indirect benefits must be answered by reference to the basic concepts of value.

Definition of Flood Losses and Benefits

It becomes necessary now to make some definitions of what constitute valid flood losses and benefits. The economic effect of floods touches such a multitude of diverse phases of human activity that, unless some guiding principles are established for analysis, confusion and, consequently, erroneous conclusions will be deduced. That these principles must be basically sound and in accordance with well-established economic doctrines that are recognized to be fundamentally correct goes as a matter of course. Because of the aforementioned diversity of flood losses, the principles and definitions can be only the broadest.

Flood losses may be defined as those losses arising from the following exigencies:

(a) *Any Destruction or Damage Caused by a Flood to the Existing Real or Personal Property of a Community.*—This includes all physical and such intangible property as may constitute a part of the total wealth of the community. As a rule, it will not include the loss of the evidence of indebtedness; only where the debtor is outside the damaged community and when the debt cannot be proved except by the papers lost can the value of the debt be allowed as a valid loss, and in that case it is a loss only in that community and not in an area including both the debtor and the creditor.

The operation of this rule can be shown clearly by an illustrative property account, which may be called the Community Property Account (See Fig. 1).

Community Property Account

(Debits)			(Credits)		
Date	Item	Amount	Date	Item	Amount
	Property of A Property of B Property of C	X_1 X_2 X_3		Community wealth	X_n
	Total	X_n		Total	X_n

Fig. 1

The account must balance. Hence, any loss that affects the property of *A* (who, it is assumed, has no connection with the others) will result in a decrease of the debits and necessarily will cause a reduction on the credit side of the account, which represents the total community wealth. Suppose again that *B* sustains a loss which is a payment that goes entirely to *C*. There is no change in the debits, and consequently there will be no change in the community wealth.

(b) *Loss of Earnings or Loss of Services.*—Earnings, whether they are wages, salaries, or professional fees, are compensation for services and are an economic commodity, as are material goods. It follows, therefore, that loss of services constitutes an economic loss to the community, but that both loss of services and loss of compensation should not be counted is brought out by considering a Community Income Account similar to the Community Property Account in Fig. 1. Assume that *D* works for *E* and that *E*'s plant is closed because of the flood. In this case *E* loses the services but saves the payment of the wages, and *D* loses his compensation; there are two individual losses and one individual gain, which leaves one net loss to the community—the loss of *D*'s services, which have the value of the compensation. This rule will be applied later in the consideration of business losses.

(*c*) *Increased Expense of Usual Operations.*—Floods interfere with normal operations and cause increased expense either without, or in addition to, other damage. This situation is likely to be encountered in the utility field, which is obliged to maintain service at all times regardless of the emergency. Certain functions of the municipal governments are likewise greatly increased in periods of flood. A somewhat similar type of loss exists in all commercial or industrial firms. They have certain overhead expenses, such as taxes, rent, insurance, and so forth, that must be paid regardless of interruption of income. When the interruption is a flood, the expenditures for fixed charges or overhead may be fairly charged to flood losses.

(*d*) *Diminution of Capital Value of Real Estate.*—This type of loss is emphasized in the case of residential property and is applicable to nearly all nonproductive or consumptive property. The repairs of flood damage, which constitute an added expense, and the personal risk involved, make this property less desirable for use. The subjective evaluation of this lessened desirability is reflected in the capital value by diminishing it. Productive property is subject to the same capital loss as a result of a flood not previously experienced or expected. If such property is located on a site known to be subject to floods, that added expense should be foreseen and the capital value adjusted or fixed on the basis of such anticipated expense, which becomes a charge against income. For all property, however, this diminution of property value should be considered as a nonrecurring loss if it is allowed in one flood. This type of loss will be considered again in connection with indirect losses and one method of evaluation of flood damages.

(*e*) *Expenditures Caused by the Flood Emergency or a Threat of Flood.*—These expenditures may be roughly grouped into two classes: (1) Emergency flood protection, and (2) cost of relief to flood sufferers.

Whenever a sufficient warning is had, occupants of the flood plain take steps to protect their property. Dikes may be constructed to protect low areas; machinery may be moved to high ground or to upper stories or may be protected by other means; and stocks of merchandise are raised to elevations above the expected flood. This work is undertaken before it can be known to what stage the water will rise, and entails expense—frequently heavy expense—which must be met from some source. These expenditures are properly chargeable as flood losses even though it is proved later to have been needless.

Floods invariably drive large numbers of people from their homes and cause the loss of their usual source of subsistence and shelter, which must be furnished from other sources. The refugees gain what is expended by the municipality and relief agencies, but the loss of their usual sources of subsistence and shelter is probably worth considerably more to them on account of the subjective value, if for no other reason. The full amount of relief expenditures may reasonably be taken as a flood loss.

TWO GENERAL CLASSES OF FLOOD LOSSES

For the purpose of evaluating annual flood losses and benefits, it is convenient to divide the damages into two general classes—direct and indirect. The broad basis of division is the immediate origin of the damage; but since the object of the classification is convenience rather than inescapable necessity, other factors may be given consideration that may entail variations in treatment. In the category of direct losses may be placed all damages to physical property (Class (*a*)), and the direct expenditures (Class (*e*)) for flood emergency.

In addition to the direct losses sustained by the physical property, other losses (Classes (*b*) and (*c*)) arise indirectly from many sources because of the flood. These constitute the "indirect losses." The sources of the indirect losses are as diverse as the direct. They arise in the flood zone and outside, and may occur far from the locality of the flood.

Perhaps first in importance among the sources of indirect flood losses is the interruption of commercial activity. In this respect floods are similar to fires; they stop the normal earning capacity of all commerce and industry for the duration of the high water and for whatever length of time is needed to clean the premises and repair the damage. This business loss consists of the gross business profit of the operations. It includes loss of profit, wages and salaries, all expense for overhead, and all indirect operating costs. Where no goods are manufactured or sold, no raw material or stock of goods will be used, and consequently the difference between the cost of raw materials or cost of stock of merchandise and the normal value of the goods sold will form the indirect flood loss caused by the interruption of business.

The data obtainable for computing this kind of indirect loss consist of the value of sales for the period of suspended activity, and they should be examined critically. The amount of sales should be normal for the season. Items of cost that are suspended or reduced should be omitted from the losses. It commonly happens that, after the flood has subsided, labor normally used in the business is assigned to cleaning and repairing the plant. In this case, labor costs should be charged to direct loss and not the indirect loss. For computing the indirect loss from the normal sales, rates of gross profit, less labor costs (usually), may be estimated for each line of business and applied to the data of loss of sales.

Another source of indirect loss arises in the transportation systems—the railroads and the highways. When the highways and railroad tracks are submerged, the grades eroded, or bridges damaged or destroyed, the traffic must use other, and in practically all cases, longer routes. This necessarily results in greater expense of transportation. In the case of the railroads, the cost is borne by the companies and could probably be estimated from their records, although a search would be long and tedious. Furthermore, there is likely to be some loss or at least inconvenience to the consignees or shippers and the passengers because of the longer route.

In contrast with rail traffic, the losses caused by floods to highway transportation are borne by the public. The individual losses may be little or they may be considerable, for they will depend upon how much use is made of the roads by the individual. With rail traffic, these losses arise because of rerouting and consequent longer haul. For example, it may cost 1.5 cents per mile to operate an ordinary passenger car. If, then, that car is forced to use a route 5 miles longer, and is forced to traverse it four times daily, it will sustain an additional expense of 30 cents a day for the duration of the interruption. One or several cars will not produce a great indirect loss; but the operation of many vehicles, including commercial trucks with much higher operating cost, can amount to a considerable sum in a short time.

The interruption of the services of utilities can cause the suspension of operations of business outside of the flood zone. Electric power is particularly vulnerable in this respect, because hydroelectric plants (which usually generate a part of the supply) and transmission lines at river crossings form prospective sources of interruptions.

There are other sources of indirect losses, most of which are even more difficult to express in terms of money. There is the loss of the use of playgrounds, parks, schools, churches, and similar property. Each flood brings with it a definite risk of loss of health and frequently life that can be evaluated only subjectively. No attempt can be made herein to enumerate all possible forms of indirect losses, because there are manifold sources, but the foregoing are the principal ones. Others should be searched for in each flood.

Flood Risk

Before proceeding to describe the methods of evaluating the annual flood loss, it is desirable to discuss further the economic risk of such damage. Although floods are usually more likely to occur in some seasons than in others, the time of occurrence is unknown until the rising stages may give warning of impending danger. Even that foreknowledge is available only on the larger rivers, and disastrous floods may occur on smaller streams without any indications of their approach. The magnitude, perhaps, is more uncertain than the time of occurrence. There are many areas, moreover, which may be inundated but yet have not in recorded history experienced a freshet great enough to cover them. The occupants are subject to flood damage, therefore, even though it is unknown to themselves. These people who dwell or work on a flood plain are thus liable to an unknown and uncertain expense that can be designated the "flood risk." Economically, this flood risk is in no way different from that of other uncertain catastrophic events such as fire or earthquake.

From an economic standpoint,

> "* * * risk may be defined as uncertainty in regard to cost, loss, or damage. In this definition, emphasis is on the word 'uncertainty.' Where destruction of capital is certain in connection with a business process, it can be charged up in advance as a cost. It is not a risk. When the destruction or loss is uncertain, it may be dealt with in accordance with the judgment of probabilities and presents a problem of risk."[3]

---

[3] "Risk and Risk-Bearing," by Charles O. Hardy, Inst. of Economics, Washington, D. C.

This definition fits the flood situation perfectly. Moreover, the definition may be extended a step further by defining the annual flood loss as the cost of the flood risk.

Flood risk, as well as other kinds, may be conveniently divided into two classes—property or capital, and personal risks. The first kind pertains to the loss of property or goods. It may be satisfied with the money value of goods or damage sustained. The personal risk is due to the subjective value that an individual puts on an object. It is usually greater than the exchange value. It is a value that arises from long association with the object in question, such as, for example, an old chair, store, house, or the building of a life business. The same category will cover the loss of means, employment, health, and life itself.

The capital loss can be evaluated satisfactorily on an annual basis when the property damage is known; but the personal risk can be evaluated only indirectly, either by determining the value from the adverse effects of the risk or by determining what the individual will pay to ameliorate his situation. This paper is concerned primarily with the property risk.

Since flood risk depends upon uncertain events, its evaluation must be based upon some expression of the probabilities of occurrence. These estimates of probability fall into three classes,[3] namely: (1) Mathematical *a priori*, (2) statistical, and (3) judgment. In a further statement, Charles O. Hardy states that judgment is only a crude application of the statistical method. In determining the probability of flooding, unaided judgment should be used only when there are no other means possible.

On the other hand, mathematical *a priori* methods cannot be used to determine the probability of floods, and hence that method is eliminated from further consideration. There remains, therefore, only the methods of statistics, which can be based on the records of flood data that have been compiled. It is on the principles of statistics that the methods of evaluating the annual flood losses, discussed in this paper, are based.

THE COMPUTATION OF ANNUAL FLOOD LOSSES

The annual flood loss has been defined as the cost of the flood risk, and it may be considered as an expense to be met in the same manner as any other similar cost, such as fire losses. The cost is not uniform in the absence of insurance but varies as time and chance provide the floods. The risk of floods is continuous, however, the same as that of any other catastrophe; when it occurs the damage is done and the expense must be met.

The intermittent and sometimes heavy cost of floods may be reduced to an annual basis in accordance with the mathematical expectancy as expressed by the formula

$$A = p\,D \text{.........................} (1)$$

in which A is the annual flood loss, p the probable number of floods per annum, and D the total damage caused by the floods. Eq. 1 is well known and is the mathematical expectancy of payment or cost of a chance event. The number of floods per annum can be taken from a frequency curve which must be computed from a record of flood discharge. The damage, D, must be taken from a stage-damage or similar curve that has been constructed from data obtained from a field survey.

Frequency Curves

It can be seen from Eq. 1 that the probability of a flood is one of the two essential factors entering into the computation of the expected annual flood loss. Therefore, it is advisable that some consideration be given to this matter. Although data of floods will be approximations at best, they should nevertheless be analyzed carefully, and the frequency should be computed by the best possible means.

Many methods of computing flood frequencies have been proposed, some purely empirical and others partly based on the mathematical theory of probability. It is plain, however, that the importance of accurate evaluation of the annual flood losses is such that the frequencies should be based on a sound mathematical and hydrological theory. Although it is not the purpose of this paper to enter into a long discussion of the various methods of computing frequencies of floods, it seems, nevertheless, desirable to describe briefly the applicability of the theoretical methods.

Floods are the result of extraordinary rainfall, or rapid melting of snow, or a combination of both. Behind each of these two primary causes there must function a long chain of preliminary events, each of which has its own peculiar variations and may operate in various degrees in the combination of circumstances that produce the flood. In fact, a peak is a result of fortuitous combination of favorable chance variations of the usual meteorological events. For that reason, data of floods, both of magnitude and of number, are amenable to treatment by the mathematical theory of probability.

Since the magnitude and the number of floods are the result of chance circumstances, one cannot expect a given series to be duplicated. The engineer must anticipate that there will be floods in the future as in the past; but when, or how big, a given flood will be he does not know; and he has no way of learning. On the other hand, he may expect a similar distribution of floods (that is, a similar proportion of high, moderate, and low peaks in a given period), and from the distribution he may expect approximately the same average and the same mean square variation (or coefficient of variation). These two quantities constitute the first and second statistical moments. If the record is long enough, it is also reasonable to anticipate similarity in the higher statistical moments, and from a record of moderate length the moment may be obtained with suitable accuracy. The frequency of floods then may be computed from the moments by the mathematical theory of probability.

Several sound methods exist that may be used for the computation of frequency curves. First in point of publication is the method proposed by H. Alden Foster,[4] M. Am. Soc. C. E., for which the probability functions of Karl Pearson formed the basis. Secondly, J. J. Slade, Jr.,[5] presented an asymmetrical probability function that can be used appropriately for computing frequencies of peak discharge or volume. If the data of floods consist of stages only, a frequency curve can be computed readily by means of a Gram-Charlier probability series.[6] In using the same data these functions will yield closely comparable results. They agree very closely for the range of data which the former will cover. Likewise Professor Slade's function gives results practically identical with those obtained by means of a Gram-Charlier series when the data consist of stages.

---

[4] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 142.

[5] *Loc. cit.*, Vol. 101 (1936), p. 35.

Before attempting to construct any frequency curve, the records of discharge should be examined carefully to determine whether or not the data of crests, especially in the earlier part of the period, are comparable to those of current observation. The regimen of streams, even in the natural state, changes more or less as time passes. The greatest danger is that conditions affecting stream flow may have been altered by human agencies in the development along the bank in a way that changes the stage-discharge relationship or even modifies the discharge. In such an examination, each record must be treated on its merits and given individual attention. Nevertheless, there are some sources of modification for which a special search should be made. Some of these factors modify discharge and the resulting stage, and others change the stage-discharge relationship so that only the stage is affected.

First, there may be diversion from one watershed to another. This diversion is most likely to occur in projects for municipal water supply but may arise in development for irrigation or water power. All discharges will be reduced, but the low-water flow will be affected most appreciably. If the diversion works provide a spillway into the old stream, the effect on floods may be relatively small or even negligible.

Second, there may be storage reservoirs upstream from the gaging station. These reservoirs will modify all floods to an extent that will depend upon the capacity of the reservoir and the drainage area above. Small reservoirs well up in the headwaters and controlling only a small part of the watershed may be neglected. The effect of the larger ones, especially those closely above the gaging point, must be considered. The best procedure, perhaps, is to compute the probable effect the reservoir would have had on the crests that occurred previous to its construction. At best, however, a new uncertainty has been introduced in the data by the vagaries of the human operation of the reservoir.

Third, the construction of levees for local flood protection will modify greatly the stage-discharge relationship, although it will not affect the rate of discharge appreciably unless much valley storage is lost.

Fourth, encroachment on the channel by bridges, highway and railroad grades, and the construction of buildings on the flood plain and channel modify the crests chiefly by causing backwater which changes the stage-discharge relationship.

Fifth, the construction of navigation dams and run-of-river power plants that have little or no storage affects the crests to some extent. It is probable that works of this type will have little or no effect on floods downstream other than perhaps to shift the time of crest slightly. The effect on the reduction of flood crests of power dams with pondage only is likely to be overestimated, but it should be investigated.

---

[6] "Probability and Its Engineering Uses," by Thomas C. Fry, D. Van Nostrand Co., Inc., N. Y., 1928.

Sixth, there is usually some intermittent erosion and shifting of the channel. This situation is likely to occur when the stream flows through a loose geological formation such as alluvial silt. The rate of flow will not be affected, but the stage-discharge relationship is very uncertain. Unless the entire record can be worked over with reliable discharge rating curves or the entire discharge can be based on frequent—almost daily—measurements, it is better to compute a frequency curve of stage only.

Seventh, there are some other events that must be looked for, such as ice jams and dam failures. The effect of the former should be included in frequency curves to be used with damages possible during the spring or winter seasons. The latter are so rare that the effect should be eliminated from the flood record.

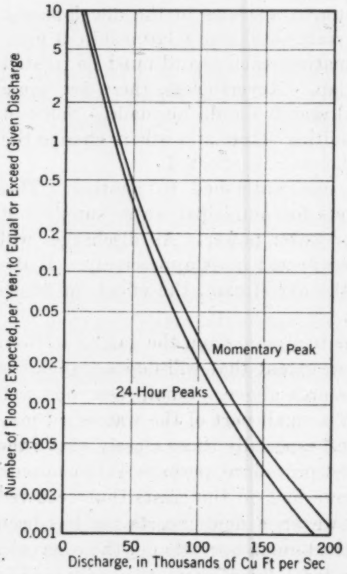

Fig. 2.—Flood Frequency; Merrimack River, Lawrence, Mass.

The preferable form of frequency curve is obtained by plotting the number of peaks or floods expected per year against magnitude, either of discharge or stage. Quantities needed for the computation of the annual loss may then be read directly from the curve. Fig. 2 shows a sample curve computed from the records of the Merrimack River at Lawrence, Mass.

Because the potential damage causable by floods is not uniformly distributed through the year, it is sometimes necessary to make frequency curves for floods experienced in different seasons. The most satisfactory manner of accomplishing this is to use the data of floods to compute separate curves for the different seasons. This may be done where a long record with ample data exists. For each given frequency the sum of the number of floods expected during each season or fraction of the year should equal the total number for the year.

It may be necessary to make seasonal frequency curves from data of those periods during which a single cause of floods, such as melting snow, operates exclusively of others. Such a condition prevails in regions where early spring floods arise from melting snow prior to a season when intense rainstorms can occur. In other sections, such as the southern parts of the United States where heavy rainstorms are the sole primary cause of floods, the annual frequency curves may be divided into seasonal curves on the basis of the yearly distribution of the peak data.

STAGE-DAMAGE CURVES

A stage-damage curve represents the losses caused by floods at various stages. An example, for Lawrence, is shown in Fig. 3. It is assumed in this example, and in all similar curves, that the total direct loss caused by a flood is given at any stage, regardless of how, or from what data, the curve was constructed. It may be constructed from data obtained by a survey of actual damage caused by one high flood, or from the damage data of a number of floods that have occurred at different times and to diverse stages, or it may be computed from the estimated potential damage. In any case, a point on the curve should give the total direct loss from a flood to the corresponding stage.

A variant of the stage-damage curve is one which shows the loss plotted against peak discharge. The discharge-damage curve will frequently facilitate computation of the annual loss.

The stage-damage curve links the damage to the frequency of floods through the elevation of the property to the stages of the stream. The essential data of each item of damage required for its construction are the location and the elevation of the damage above a datum plane which can be correlated with stages of the stream. The elevation of damage above ground or below a visible high-water mark can be obtained by measurement. All variations of elevation, whether caused by difference in topography or by construction of the property, are taken into account by the stage-damage curve.

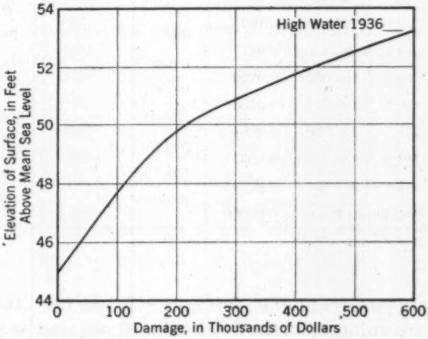

FIG. 3.—STAGE-DAMAGE CURVE FOR LAWRENCE, MASS.

An example of the computation of the annual loss of an urban area is shown in Table 1(*a*). The frequencies are taken from Fig. 2 and the damage from Fig. 3. The stage, 53.1 ft (Table 1), is the maximum that has been experienced. The damage of greater floods has been limited to the same amount in this computation, as a matter of conservatism.

ESTIMATING FUTURE FLOOD LOSSES

Of course, data of flood damage can be obtained only for floods that have been experienced; there is no other basis on which data of actual, experienced losses can be had. Yet, since comparison must be made with future costs, it becomes necessary to use the data at hand to estimate future losses and benefits also. The compiled data should be examined carefully, therefore, to eliminate nonrecurring losses and sometimes to make adjustments for past economic growth or expected future trend of development.

Damage that manifestly will not occur again should be eliminated from the computation of annual losses. In this category may be included (1) bridges that have been washed out and will not be replaced, or new structures that have sufficient elevation or waterway capacity to obviate all future danger; (2) dams that will not be reconstructed after failure; (3) other buildings that have been destroyed and will not be replaced; and (4) areas that have been evacuated and cannot be reoccupied because of physical conditions or legal restrictions. Items of damage that are eliminated should be scrutinized carefully and cast out only where it is reasonably certain that other developments, subject to similar damage, will not take their places. If replaced structures are vulnerable, the flood risk will remain the same as before the flood. Furthermore, unless some restrictions are made by conversion of land into parks or other legal enactment, evacuated areas may be reoccupied and the flood risk re-established. Moreover, there are unusual losses in nearly every flood so that an item should not be thrown out simply because it is unique.

TABLE 1.—ANNUAL LOSS FROM FLOODS, LAWRENCE, MASS.

Stage, in ft	Discharge, in cu ft per sec	Frequency (No. per Yr)		(a) Natural Conditions			(b) Reduced 1 Ft		
				Damage (Thousand Dollars)		Annual loss (dollars)	Damage (Thousand Dollars)		Annual loss (dollars)
		For discharge	For interval	For discharge	For interval		For discharge	For interval

Maximum Flood		0.00000		590			446		
Total annual loss		....	....	....	....	28,960	....	....	12,972

It is impossible, of course, to predict definitely what economic development will take place in the future, but at least the trend must be examined in extending flood losses to compare with future costs. In this respect, flood-control works are on an equal footing with other structural developments, such as hydroelectric plants, railroads, large office buildings, and industrial plants. All must be constructed in the light of present economic conditions plus what trend may be predicted safely.

A key to economic development may be found in the growth of population, since all such activity arises from satisfying human needs. The growth of population in the United States apparently has become stabilized following the full settlement of the country, and relatively small changes may be expected in the future except in localities where a new industry has settled or some other attraction to development exists. These factors may be determined by investigation. Except in special circumstances, it will be in the interest of conservatism to assume no increasing losses in the future.

Some difficulty will be encountered in correcting or adjusting for seasonal changes in the potential flood damage. Usually the seasonal fluctuations of the retail trade are too small to be considered in view of the probable error of the flood-damage data. There are some industrial activities, however, which have a seasonal trend that may require some special consideration. Activities such as fairs, which commonly last only a week or ten days, will subject much perishable property to loss in event of a flood, if the grounds are in an area liable to inundation. Plainly, such potential loss cannot be computed with an annual frequency curve but should be used with the number of floods to be expected during the period of such activity.

Agricultural Losses

Other than crops, rural and agricultural losses can well be treated in the same manner as urban damage. The reaches may be longer and the losses will be more widely scattered, but otherwise there is no essential difference from urban damage, and there is no material seasonal fluctuation of risk. The outstanding source of such seasonal changes, of course, is agricultural crop losses, which must be given special consideration.

In contrast with urban and other rural damage, potential crop losses resulting from floods vary greatly from season to season; and they vary with the area flooded in a manner distinct from other damage. Beyond a relatively shallow depth, they do not increase with added inundation, for, if a crop is flooded sufficiently to be a total loss, it suffers no further damage by deeper water. These factors necessitate different treatment and entail the use of two other curves instead of the stage-damage curve. The first of these is the "area-flooded" curve, which represents the area of land flooded at various stages. The second is the "crop-loss" curve, which shows the potential loss of crops for the various seasons of the year.

The area-flooded curve may show the cultivated area inundated in a given reach or (preferably) the total area. The latter is the more constant value. The area flooded depends upon the stage and the topography of the valley or flood plain. Accurate topographic maps are necessary for its construction.

The risk of crop loss varies from nothing in the winter season in the northern latitudes to full, or nearly full, value of the harvested crop in summer. In southern or warm regions there may be some loss throughout the year because the work of preparation, such as plowing or the application of fertilizer, may be nullified by floods. The maximum monetary loss, of course, will depend also upon the value of the crop.

The "crop-loss" curve, which shows this seasonal flood risk, should preferably give the loss per acre, for clarity and convenience in computation. A curve may be used for each individual crop, or one curve may be a combination of several crops weighted by the average plantings of each. The example in Fig. 4 illustrates a curve of the latter type. Data needed for the construction of these two curves include the following:

(*a*) Total area within the reach or area in which crop losses are to be computed;

(*b*) The average proportion of the total area that is cultivated;

(*c*) The average acreage devoted to various crops raised in the area;

(*d*) The average cost of preparation of land and drop at various seasons;

(*e*) The average prices of the harvested crops;

(*f*) The dates or seasons of various farm processes performed in the raising of crops (that is, planting, cultivation, harvesting, and plowing); and

(*g*) Latest date on which a crop may be replanted so as to produce a harvest.

Items (*a*), (*b*), and (*c*) are used in the construction of the stage versus area-flooded curve, and items (*d*) to (*g*) are required for the crop-loss curve.

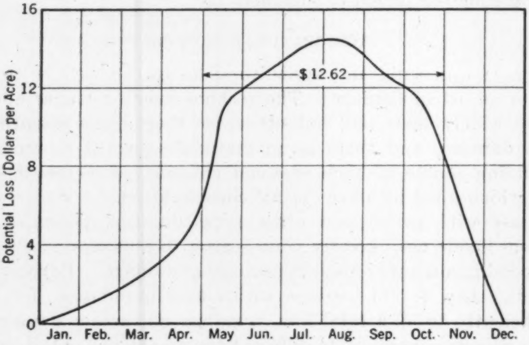

FIG. 4.—POTENTIAL CROP LOSS; REACH ON THE LITTLE RIVER, ARK.

The area-flooded curve is based primarily on the total area of the reach, since the land uses are more easily checked on that basis. Aside from that reason, it could be made to show cultivated area only. A computation of annual loss is given in Table 2.

COMPUTATION OF INDIRECT LOSSES

Indirect annual losses cannot be computed on the foregoing basis, primarily because the relation between the stage and loss is not constant. Other factors enter, which differ with the source of the indirect loss. Business losses, for example, depend also upon the time during which the plant is closed for repairs, which period will vary also with the nature of the business as well as the extent of the physical damage. The cost of rerouting of traffic will depend upon the length of available detours and the time needed to make repairs. Each source of indirect loss contains some other factor to affect the relationship.

There appears, however, a somewhat more constant, closer relationship between total direct and indirect losses of individual business concerns, since greater indirect losses will be sustained when the more extensive damage must be repaired. On the basis of this relation, a ratio of indirect to direct damage may be computed from the field data, adjusted if necessary, and applied to the annual direct losses. For example, the indirect loss in a particular flood may amount to 40% of the direct damage; then the total annual loss will equal 140% of the direct annual loss.

TABLE 2.—Crop Loss for Period from May to October, Reach on Little River, Ark.

Stage, in ft	Frequency, No. of Floods per Yr		Land Flooded, in Acres		Crop Loss		Annual loss
	For stage	For interval	For stage	Mean for interval	Per acre	Total	
26.0	0.608		0				
		0.257		270	$12.62	$ 3,407	$ 876
27.0	0.351		540

36.0	0.00020		2,180				
Total annual crop loss for the period							$5,430

Benefits from Flood Control

The primary source of benefits from protective works is the elimination of flood losses. The benefits are of the same diverse nature as the flood losses, and various means must be used to evaluate all types. Floods are recurrent phenomena, and therefore the risks are continual although the damages are intermittent. The losses, or cost of the risk, are a charge against income; that is, they are an expense which, without protection, must be paid, although it is irregular, and for which nothing is received in return. The benefits are equal to the losses eliminated. In accordance with this principle, the direct annual flood benefits from works giving complete protection will be identical with the total annual losses.

The annual benefits obtaining from works (reservoirs, for example) which may give only partial protection may be computed to the extent that floods are reduced. For example, suppose that a reservoir had been constructed which would reduce all floods at a given point by 1 ft. The benefits result from reducing each flood that may occur and thereby save a part of the possible loss. For a given flood the same causes, or substantially the same in effect, will operate to produce the given peak after the construction of the reservoir, as previously. Therefore, the frequency, expressed as the expected number of floods per year, will remain the same; since the flood is reduced 1 ft, however, the damage will be taken from the stage-damage curve at a point 1 ft lower than the natural stage. The stage at which damage begins will remain the same so that all floods above that point to the limit of the reduction will be reduced below the danger point. The computation of the annual loss is repeated with control (see Table 1(*b*)), and the difference in annual loss under the two conditions is the annual benefit:

Annual loss under natural conditions (Table 1(*a*))	$28,960
Deduct annual loss, with reduction of 1 ft (Table 1(*b*))	12,970
Annual benefits with 1-ft reduction	$15,990

The damage center is the same as that used for natural conditions (Table 1(*a*)).

Reservoirs will not reduce all floods equally. Small floods below the danger point generally will be passed with no reduction. A reservoir usually will be designed to control a specified "design flood," the reduction for which will probably be the maximum since larger floods will pass over the spillway with a smaller relative reduction. A curve will be required to show the reduction obtainable over the full range of floods. The computation of annual loss is substantially the same except that the variable reduction obtained from the curve will replace the uniform reduction. As before, the annual benefit will be the difference in annual losses obtained before and after control.

Levees will eliminate all direct losses caused by inundation up to the stage at which they are overtopped. Beyond that stage the loss is as great as if there were no protection. The annual benefits will equal the annual losses below the elevation of the top of the levee or wall.

Losses and benefits can be computed graphically from a diagram such as is shown in Fig. 5. Values on the ordinate scale are the numbers of floods per year, and on the abscissa, the damage caused by a peak at the corresponding stage. The area under the curve (area *O A B C O*) then represents the total annual loss from uncontrolled floods. Next, a similar curve is constructed for losses after control (area *O D E F O*, Fig. 5). The area between the two curves (area *A B C F E D A*) represents the average annual benefits.

Accurate distribution of benefits is possible by the foregoing analysis. It may be desirable in some cases to determine the benefits accruing from two or more means of protection. It is only necessary to fix the range of stage through which each method of protection and the benefits obtained may be readily computed. The benefits derived by each type of protection will be the reduction of losses through the range of stage in which it operates. It should be remembered that the benefits per uniform increment of stage vary in accordance with the frequency of the floods expected.

In some cases, the benefits from protection of agricultural land are obtained as average value per acre. No objection can be raised against this, provided that it is used only where the total for the given area can serve equally well. It is an erroneous step, however, to assume that the higher areas covered by the greater floods will have the same average annual benefits as the lands at lower elevations. For example, levees may protect to elevation *a*; land above stage *a* will not yield the same average annual benefits with protection as those below for the reason that the latter are more frequently flooded.

EVALUATION BY ESTIMATING DEPRECIATED PROPERTY VALUES

In the foregoing evaluation of flood losses and benefits, the entire process was predicated on the basis of an annual loss or expense of risk, and therefore a charge against revenue or income. In contrast with this method, evaluation of flood losses has been made on a capital basis, which consisted essentially of an estimate of the decrease of capital value of property caused by one large flood. This process has been used in computing the value of flood protection and hence must be given some consideration.

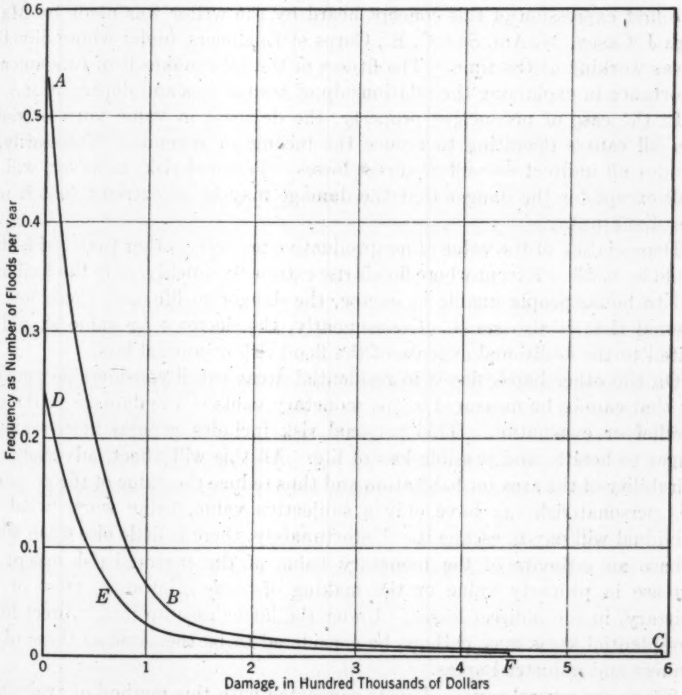

FIG. 5.—GRAPHIC COMPUTATION OF FLOOD LOSSES AND BENEFITS, LAWRENCE, MASS.

An appraisal is made of the affected property after the flood to estimate its value then and the value as before the inundation. The difference between the two values is taken as the flood loss and, if damage is fully eliminated by protective works, the benefits to be obtained. These appraisals must be considered primarily as a sale value or equivalent since construction costs will not be materially affected by the flood risk of the completed structures. For present purposes it will be assumed that the difference in appraisals includes all the costs.

Except for the effect of the construction costs, which constitutes a factor tending to resist change, the value of property will depend upon the income that can be earned by productive property or upon the desirability for use intended in the case of nonproductive property. This value will be manifest in the sale price of property, which should correspond to the appraised values. If a piece of property becomes subject to a flood loss, its desirability either for profit-making, habitation, or other use becomes less, and its capital value falls. Therefore, the appraised value or sale price will be less. The decrease in capital value, or depreciation of value, is seen to be simply a subjective evaluation of the total annual flood loss in terms of the capital value of the property. (The first expression of this concept heard by the writer was made by Major Hugh J. Casey, M. Am. Soc. C. E., Corps of Engineers, under whose direction he was working at the time. The fitness of the idea makes it of fundamental importance in explaining the relationship of annual loss and depreciation.)

In the case of productive property, the decrease in value must originate from all causes operating to reduce the income or revenue. Necessarily, it includes all indirect as well as direct losses. Personal risk, however, will be small except for the danger that the damage may be so extreme that it may cause bankruptcy.

Depreciation of the value of nonproductive property, other than residential, should be small. Except where floods rise extremely quickly, or in the buildings used to house people unable to escape, the danger to life and, therefore, the personal risk, is also small. Consequently, the decrease in value should be limited to the additional expense of the flood risk or annual loss.

On the other hand, floods in residential areas entail considerable personal risk that cannot be measured in the monetary value of the damage or the cost of relief or evacuation. This personal risk includes general inconvenience, danger to health, and possible loss of life. All this will affect, adversely, the desirability of the area for habitation and thus reduce the value of the property. This personal risk can have only a subjective value, being worth what the individual will pay to escape it. Unfortunately, there is little else upon which to base an estimate of the monetary value of the personal risk except the decrease in property value or the making of some allowance, more or less arbitrary, in the indirect losses. Under the latter assumption, indirect losses of residential areas may perhaps be considered to be the same as those of the business and industrial areas.

There are several serious defects connected with this method of evaluation, however, which preclude its acceptance for general use. Depreciation of value will be quite high immediately after a flood, especially if it is the first experience in the area; but, as the hysteria subsides, property will regain a part of the loss in value, and, as time erases the memory of the flood and new people come into the area, values will probably reach practically their former levels. The decrease in value will depend upon the time elapsed since the last great flood, but the real flood risk will continue as before unless some means of protection have been provided.

The capital-loss method bases the estimated damage on a single flood. As is well known, there are other floods of lesser magnitudes and possibly others of greater, and therefore there is only the faintest chance that the total damage of a single flood can equal the capitalized value of the annual flood loss. The annual flood loss or risk sustained is the total of all floods, great and small—not from just one large inundation. Furthermore, the damage caused by one flood cannot be compared properly with the capital cost of protection because of the element of time, which enters through the frequency of floods and the interest on the investment.

In order to determine the capitalized value of the annual flood loss, the latter must first be obtained by some means, after which there would be little reason to capitalize it. It may be said that the annual cost can be obtained from the total flood loss by applying a suitable rate of interest. What rate? This question must be answered whether the annual loss is desired from the total damage or the latter is obtained by capitalizing the annual loss. In either case the rate must be selected arbitrarily or on a basis not relevant to the flood risk, which action will yield a result little better than a guess.

Other Benefits from Flood Control

Flood-protection works frequently result in benefits other than the elimination of the losses discussed herein. A source of benefit may be found in some localities in the possible appreciation of land values when an area is adequately protected from a recognized flood menace. The lands subject to such appreciation must be situated adjacent to, or in, a highly developed locality where other land is scarce so that there can be little or no doubt about the utilization of the land once it is protected. Appreciation of land values opens a way to assume highly speculative returns as benefits for protective works, and for this reason such possibilities should be examined with great care. Conservative estimates of benefits will eliminate the assumption of increased land values except in the most favorable cases. Before it can be allowed, there should be in view a need for the land and a manifestly ready market, two conditions which practically limit appreciation to favorably located urban property. At least for the present the alleged overproduction of farm products should be a sufficient objection to allowing appreciation of rural lands as a benefit of flood protection.

Occasionally a vast, ill-defined, and unevaluated benefit (designated "social benefit") is advanced as a reason for flood protection. Social benefits are essentially the total elimination of all the foregoing losses, including the personal risk. Except the latter, all such benefits can be evaluated by some means. The value of the personal risk can be evaluated subjectively only, and will depend upon what the community will pay to eliminate it. Certainly a community that has voted against contributing as little as the right of ways has stated in no unequivocal terms that the flood risk, personal or other, has no value for the people living there.

When flood protection is sought by means of reservoirs, other benefits may (in favorable cases) be obtained. In large reservoirs there may be storage for power, or sanitary, or navigational, uses by augmenting the stream flow in low-water season. Pools may be maintained at fixed elevations so that more or less permanent lakes are created, which may be utilized for summer resorts or other forms of recreation. All these, however, are by-products peculiar to one type of protective works, and to certain favorable sites, and will assist in reducing the cost chargeable to flood protection if they have a recognizable value. They are not obtainable by the reduction of flood losses, however, and for that reason are not considered further in this paper.

Collection of Damage Data

The collection of data of flood damage is a task that requires care, experience, and a broad understanding of economic values in all phases of human activity. Much of the data must necessarily be estimated, particularly the indirect losses; and, although there are many cases of actual costs obtainable shortly after a flood, considerable judgment necessarily must still be exercised. Reliable judgment can be derived only from experience. The compiled data should be as full and complete as can be secured with reasonable effort. Information of certain kinds is necessary, and other kinds are desirable for guidance of judgment or basis of estimate.

The essential data required for computing the value of total damage and the annual loss fall into four distinct classes: (*a*) Monetary value of the damage sustained; (*b*) elevation of the property above a fixed datum which is, or can be, correlated with the available data of flood crests; (*c*) location of the damage; and (*d*) stage or discharge of the flood. In addition to the foregoing data, more information is needed to support the primary data of damage. This information is extremely varied, since it pertains to every variety of economic activity, and can be classified as follows—

For buildings: Approximate dimensions, condition, type, and material of construction.

Bridges: Purpose, type, dimensions, material, and approximate age and condition.

Highways and railroads: Type of surface, length affected by the flood, and amount of traffic.

Business losses: Nature of business, approximate payrolls, annual sales or production, and gross profits.

Acknowledgment

The ideas and opinions expressed herein have been developed by the writer while engaged in work on flood-control studies in the various district offices of the U. S. Engineer Department. They have grown with the duties undertaken and have been shaped by innumerable conferences with many colleagues. The opinions expressed herein, however, are those of the author and do not necessarily reflect the official view of the U. S. Engineer Department.

DISCUSSION

E. L. Chandler,[7] **M. Am. Soc. C. E.**—Probably there will be no dissent from a statement that the construction of a flood-protection project should not be considered justifiable unless the resulting benefits will exceed the cost. Benefits include the elimination of prospective losses directly attributable to floods, the expansion of existing facilities, and the development of new areas, which will result from improved conditions.

The author refers to "The losses from which the benefits are computed * * *" (see "Introduction"), and predicates his study on the thought that "When the losses are known, the annual benefits can be computed and compared with annual costs." This seems to be a limited and ultraconservative point of view. Any full measure of benefits must include not only computations covering tangible losses but an estimate of future expansion and development of potential resources that will be made available by reason of flood protection. Mr. Foster has not ignored this phase of the subject, but the writer is of the opinion that strict adherence to the methods advocated is likely to result in overemphasis of the specific "losses and damages" due to floods under existing conditions, at the expense of fuller consideration of the many indirect benefits and of benefits to be anticipated from potential developments that will be encouraged by flood protection. Any public development should be built with an eye to the future, and this is especially true of flood-protection works.

The writer realizes that an estimate of future benefits is a matter to be approached with caution. It is entirely possible to rise to flights of fancy that may seem to warrant expenditures for flood-protection works which should not be built. Conservatism must be exercised in making computations contingent on prophecy.

It happens that there is no question as to the serious need for flood protection for Chattanooga, Tenn. Careful estimate indicates that, with the existing development of the community, measurable damages that would result from the maximum flood to be expected would amount to between two and three times the cost of protective works. On the other hand, there are thousands of acres of land within the city limits that are unusually well adapted for industry and business developments except for the flood menace. These areas, which are well located for service by railroad, highway, navigation, and utilities, now stand idle. No surrounding territory is available that will compare favorably with these areas after they have been guaranteed freedom from flood. No measure of the benefits to be gained from flood protection would be complete without an estimate of development to be confidently expected as the result of protection. Although such estimate is not required to prove the necessity for protection at Chattanooga, it may easily happen that, in other instances, economical justification for worthy projects might fail of recognition unless future benefits were given due weight.

---

[7] Care, Chas. T. Main, Inc., Wilmington, Del.

The writer's thought may be summed up by the statement that, although it is poor economics to build works that cannot be justified by the benefits to be received, it is also poor judgment to refuse to make expenditures because of failure to recognize a full measure of benefits that would be gained.

The author states (see heading, "Some Definitions of Wealth and Value") that "value * * * may be defined or measured as the quantity of other goods that may be given or received in exchange * * *," the "other goods" being, in general, money. Again, in referring to the appraisal of property values, he states that "These appraisals must be considered primarily as a sale value * * *" (see heading, "Evaluation by Estimating Depreciated Property Values"). The true value of a piece of property is not necessarily its sale value. Mr. Foster recognizes this elsewhere in his paper, but the writer wishes to place particular emphasis on the fact. It is a common saying that "a thing is worth what you can get for it." Probably such a statement is satisfactory for the purposes of the real-estate dealer or merchant, or the casual buyer or seller, but it should not serve as a criterion for an engineer studying the economics of a project for flood protection; nor will it serve for appraisals of properties to be used as a basis for special benefit assessments in the case of assessment districts. Many factors may tend to render sale price inaccurate as a measure of value for the purpose at hand. Sale prices during boom times or during a period of depression would scarcely be proper. An influence which, perhaps, is more pertinent is the lapse of time since the occurrence of a flood of considerable magnitude. The author correctly states that a marked depreciation of value will follow the occurrence of a serious flood, and that, on the other hand, if a considerable period of time elapses without disastrous flooding, the sale value of properties will reach heights greater than the true values, due to the ignorance of property owners as to potential danger.

Mr. Foster mentions these circumstances under his discussion of evaluation of losses on a "capital basis" and concludes that they "preclude its acceptance for general use" (see heading, "Evaluation by Estimating Depreciated Property Values"). The writer does not agree with this statement. The "capital basis" method affords a feasible and valuable approach to the problem in many instances, particularly in the case of urban communities where complete protection is to be provided. Mr. Foster states that "The capital-loss method bases the estimated damage on a single flood." This is a limited approach. A study based on the effects of a single flood could scarcely be considered adequate.

In this connection the author states that "An appraisal is made of the affected property after the flood to estimate its value then and the value as before the inundation. The difference between the two values is taken as the flood loss * * *." Why "after the flood"? Probably Mr. Foster has in mind the historic apathy of flood-menaced communities. Generally, this has been such that no flood-protection works have been built except in the wake of serious floods, with the result that appraisals of property values and estimates of benefits have been made while the memory of flood disaster was fresh in mind. It is hoped that Chattanooga will prove to be one exception to this distressing rule. In such event, the situation will be the reverse of that suggested by the author. There has been no serious flood at Chattanooga for a long time and none of consequence since the community reached its present state of development. Flood-protection works have been planned and the Chattanooga Flood Protection District appraisers are faced with the problem of determining values now when the gravity of the flood menace is not generally recognized. Such values must be compared with an estimate of the enhanced values that will result from flood protection. Regardless of which conditions prevail, it is very evident that sound appraisal judgment is necessary.

The author states (see heading, "Benefits from Flood Control") that

> "Levees will eliminate all direct losses caused by inundation up to the stage at which they are overtopped. Beyond that stage the loss is as great as if there were no protection. The annual benefits will equal the annual losses below the elevation of the top of the levee or wall."

This thought should be accepted only with qualification. It appears to be substantially correct in the case of protection for agricultural areas although, even there, the overtopping of a levee, with consequent sudden flooding, is likely to result in losses far greater than those that would result from a flood of corresponding magnitude if there were no protection at all. In the case of protective works for urban communities, levees that would give anything less than complete protection should seldom be considered. The presence of an inadequate levee will furnish a false sense of security that will encourage residents to remain, with their belongings, in low areas in the face of approaching disaster. The sudden overtopping of a levee surrounding a thickly populated district is almost certain to result in loss of life and property far in excess of that which would have occurred if there were no protective works at all.

E. F. CHANDLER,[8] M. AM. SOC. C. E.—As viewed by the writer, this paper seems to be the best discussion, well rounded, with brief mention of each of the complete list of possible contributing factors or modifying phases that he has ever seen. It is especially interesting as showing the advance in accepted ideas on this subject during the twenty years, since 1920, and in particular the progress in methods used by the author himself since he first occasionally undertook such investigations.

However voluminous the base data, however elaborate and reasonable the chain of reasoning, there is no absolute certainty concerning the amount and intensity of the rainfall in any assigned future period; there is still less concerning flood flows, and less yet as to the total resulting damages in the future. Rules and formulas assist, but good judgment on the part of the engineer designing flood-protection works is also a necessity.

It can be argued plausibly that the problem of the evaluation of the benefits from flood-protection works, to determine the magnitude and expense of works advisable that will be equal to the cost of the future probable flood losses thereby eliminated, is, for two reasons, the most complicated, difficult, most nearly insoluble, of all engineering investigations. The problem confronts the engineer, however, because he will certainly have occasional floods with their ensuing losses in future years; so he is obliged to try to do the best that he can with it.

---

[8] Prof., Civ. Eng. and Dean Emeritus, College of Eng., Univ. of North Dakota, Grand Forks, N. Dak.

The first of these reasons is the uncertainty as to the actual cash loss resulting from any future flood of any assigned height; in business districts, it will vary greatly with business season, with the length of the advance warning, etc., and in agricultural regions even more with the time of year and advancement of the crops. This is not markedly more difficult, however, than the uncertainties and indefinite risks of any business venture.

The second, almost overwhelmingly large, difficulty in making advance estimates of the benefits accruing hereafter from any type or magnitude of flood-protection works lies in the extreme uncertainty as to the probable magnitude of future floods. Rainfall itself is very uncertain in its future times, amounts, and intensities. Even the annual total, in North Dakota, varies in different years from a maximum of about 150% of the normal annual to a minimum of about 50% of the normal; and short storms, of a day, few days, or few weeks, which are usually the cause of the floods, of course, are far more irregular. The portion of the rainfall that becomes floodwater is not logically a fraction of the rainfall, but a remainder after soil absorption, evaporation, small-basin detention en route, etc., have been subtracted. Therefore, doubling the rainfall in any period does not merely double the flood flow but usually multiplies it many times.

For example, in the prairie regions of North Dakota, with a many-year average total annual rainfall of about 18 in., the average total annual runoff in the streams of the region is slightly less than 1 in., although in any single year the total can easily be double the normal, or even much more than that, and in a dry year perhaps be only a quarter, or merely a tenth, of the normal annual total. In some Pennsylvania areas of 40-in. total normal annual rainfall, however, the average annual runoff is about 20 in.; and furthermore, because of the steeper sloping topography, the Pennsylvania flood crests are likely to be more accentuated.

Thus it is self-evident that in any region a slight increase in the total rainfall will presumably cause a disproportionately large increase in the stream flow. It is also self-evident that the peak height of flood flow depends on the intensity and abruptness of the rainfall (especially on small streams) far more than on the total of rainfall, and is very greatly affected by soil conditions, surface vegetation, frozen condition of soil, and a vast number of other factors, all of which the author seems to have included in his lists.

Charles B. Burdick,[9] M. Am. Soc. C. E.—The Society and the author of this paper are to be congratulated upon this concise statement and scholarly discussion of the methods applicable to the computation of benefits from flood-relief projects. Mr. Foster discusses a subject almost as important as the design and construction of the projects for flood relief. The paper deals with a subject too often neglected, partly on account of the difficulties and uncertainties that are usually involved. There may be cases in which the need for flood-relief projects is sufficiently evident to justify the cost involved in the proper remedy without computation of the benefits. Such cases, however, are very few and must necessarily involve only a few people well conversant with the facts. Even in such cases, if the interested people are called upon to "foot the bills," a very convincing case must be presented if the necessary money is forthcoming, and there must be a marked preponderance of benefits if the project is to be financed.

---

[9] Cons. Engr. (Alvord, Burdick & Howson), Chicago, Ill.

Every one reasonably familiar with stream flow realizes that a bankfull capacity of creeks and rivers is but a small percentage of the flows that the streams are required to carry as a result of unusual rainfall conditions. It is the rule that at greater or less intervals the adjoining river bottoms must be flooded under exceptional flow conditions. The fact that these occurrences are comparatively rare has led to the occupancy of the bottom lands, in many cases including costly improvements. Thus, there is a flood problem of more or less urgency upon almost every mile of the many thousands of streams that drain the continental United States.

In the days when the doctrine prevailed that works for flood relief must be built at the expense of the benefited property, such works were more or less automatically confined to the most worthy projects. In recent years, a number of exceptionally disastrous floods, which directly affected many people and of which nearly every one became cognizant through the ready means of communication today, have been instrumental in effecting state and federal legislation designed to take the burden largely from the shoulders of the chief beneficiaries of relief. It becomes especially important, therefore, to scrutinize carefully the benefits arising from such works. The public dearly loves to "get something for nothing." Immediately following a great flood, it is good politics to build works for flood relief.

Although there is no doubt that expenditures for flood relief can be justified only by prospective losses without relief, the argument sometimes has been advanced that losses have nothing to do with prospective benefits. This position has been taken by courts in some cases. The attitude probably arose from legal procedures in ordinary special assessment cases of which many thousands have been tried in which there was no way to determine benefits except through opinion testimony. Immediately following a very disastrous local flood detrimentally affecting property values, it is often practicable to secure well-informed layman testimony that certain benefits to property would arise from adequate flood protection. However, such testimony is unprocurable and would be well-nigh useless in the case of an extensive flood problem involving a large river system. There is nothing more practical that can be done than to determine as accurately as possible the probable losses of the past and to project them into the future as a guide to justify expenditures. The difficulty and the uncertainty of such a task cannot be urged as reasons to omit such an investigation. Unless a preponderance of benefits can be reasonably and clearly shown, measured in dollars, the project should not be built because there are far too many other good uses for money.

Many public expenditures are made in these days that necessarily are only subject to justification on the basis of a "hunch" that they are worth while. These often prove to be valuable improvements, although the reverse is also true. An alleged "social benefit" is a general term frequently heard and usually impossible of measurement. Flood-relief projects can be built only with dollars. Many social benefits can be accomplished only by the expenditure of dollars. Human life, sickness, and death are subject to measurement in dollars at least so far as the general public is concerned. The courts have placed values on such things in many cases, and this type of loss and prospective benefit may very properly be considered where it is an important element.

There are sometimes cases in which it is comparatively simple to show a tangible, strong preponderance of benefits based on indisputable evidence. There are many other borderline cases in which the accuracy of benefit computations may be seriously questioned. The public would do well to confine its flood-relief expenditures to cases in which the preponderance of benefits can be clearly shown.

H. K. BARROWS,[10] M. AM. SOC. C. E.—In his discussion of "Evaluation by Estimating Depreciated Property Values" the author has indicated clearly the objections to using, and difficulties encountered in attempting to use, this method of estimating flood losses and benefits, which he calls the capital-loss method. The writer is quite in accord with his views on this matter and desires to accentuate them.

If the estimates of annual flood losses substantially cover all direct and indirect losses, including proper allowance for any intangible losses, the annual depreciation losses of a property or plant, if correctly determined, will be a reflection of the sum of all these determined losses and hence another determination of the same quantity. In other words, the capital-loss method gives another, less perfect, determination of what has already been obtained by determining average annual losses, based upon the sum of direct, indirect, and intangible losses, and expressed as a capitalized amount for comparison.

In the case of the Connecticut River Flood Control project,[11] in which depreciation was included in estimating flood benefits, the following yearly figures resulted:

Class	Yearly benefits	Ratio to direct benefits
Direct	$ 853,700	1.0
Indirect	808,400	0.94
Depreciation	3,597,000	4.20
Total	$5,259,100	6.15

In this case depreciation was based upon estimates made for the 1936 flood—the largest on record—whereas the direct and indirect benefits were based upon the average yearly flood over a long period of years. Direct plus indirect yearly benefits total $1,662,100. Allowance for intangible losses may raise this total to, say, $2,000,000. The depreciation method, which is (or should be) another determination of the same quantity, gives $3,597,000. This is obviously not based upon a long-time average flood, but the greatest flood of record, of very recent occurrence, and hence inflated in amount.

---

[10] Cons. Engr., Boston, Mass.

[11] H. R. Doc. No. 455, 75th Cong., 2d Session, pp. 108–109.

The fallacy of adding together two determinations of the same quantity instead of averaging them, if of equal weight in accuracy, is obvious. Considering the uncertainty of the estimated yearly depreciation, it appears that yearly benefits for the Connecticut River project should not rationally be greater than about $2,000,000. This warrants an expenditure for flood relief of about $40,000,000, instead of about $100,000,000, which resulted when depreciation benefits were added in (as was done in the report previously cited, upon which the approval of this flood-control project was based).

The comprehensive flood-relief project for the Connecticut River is now estimated to cost about $75,000,000. It is clearly of doubtful economy and indicates that the project should not have been approved in the form presented.

The author is to be commended for his excellent presentation of a timely subject.

Roger E. Amidon,[12] **Assoc. M. Am. Soc. C. E.**—The evaluation of flood losses and flood-control benefits is an intricate and involved science. The paper by Mr. Foster is comprehensive and as complete a treatise on the subject as the writer has seen. It certainly will be widely used as reference. It approaches the category of a handbook. The author has stated with clarity the enormous number of details involved in an analysis, as well as the indefiniteness of the data upon which every study must be made. Judgment based on experience is rightly given important emphasis.

It is the object of the writer to add a word of caution to the use of the generalized formula in specific cases. The experienced analyst will not be likely to use this information in a manner that was not intended, but the inexperienced analyst may take it too literally and end up with results that are extremely erroneous or, what is more likely, he may become so "bogged down" with inconsistent results that he will throw up his hands in despair.

The watersheds of Southern California are a case in point. The methods of analysis presented by the author could be applied to a study of the Los Angeles River, or any of the larger watersheds with probably fair results. These same methods cannot be applied to the smaller tributaries originating in the steep mountains. Stage-discharge relationships are not applicable to these mountain streams because of the character of the torrential flows of muddy and debris-laden waters that debauch from the canyon mouths on to the alluvial fans below. A comparatively small flow of water may cause damage to areas that have not been damaged by previous major floods. The lodging of a boulder or several logs may cause a stream to leave an apparently well-defined channel and cut through areas that have not been touched by floods since the coming of the white man. Denudation by fire may cause a small tributary to go on a rampage from a comparatively small rainfall. With present fire detection and fighting facilities, it is improbable that a sufficient part of a large watershed would be burned at any one time to cause a flood that would be extremely abnormal for the amount of rainfall over the entire area. Even within canyons, above their mouths, the flood flows will meander over bench lands and cause damage to recreation and other developments entirely out of proportion to the stage-discharge relationship. The high percentage of solids in the flows from these canyons causes the fluid to act considerably different from that which normally could be expected from a flow of flood water. Henry B. Lynch,[13] M. Am. Soc. C. E., stated this fact clearly in 1939. In analyzing the economics of an area where such irregular conditions exist, it is necessary to give consideration to these conditions if good results are to be obtained. In areas that are bordered by mountains where denudation by fire is possible and probable, it becomes necessary to correlate the occurrence of fire with the occurrence of flood. It is possible to do this and obtain reasonable results from a study of past occurrences within the area or within adjacent watersheds. In such a comparison it is necessary to make adjustments for differences in values, types of vegetative cover, topography, etc., between the area under analysis and the one with which it is being compared. Values may be adjusted by comparing population or assessed valuation. Areas subject to this type of damage in Southern California are frequently desirable for urban development and consequently may change from an agricultural or waste area to a highly valuable residential section during the period for which the study is being made. Broad experience, judgment, and understanding are essential in making reasonable adjustments to take care of such conditions.

---

[12] Lt., 2d Air Force, U. S. Army, Fort George Wright, Wash.

The author's definition of "social benefits" does not describe what the writer prefers to term "Benefits for which it has been impossible to assign monetary values." In special cases these benefits may be so extremely important as to overshadow other benefits. Mountain canyons adjacent to highly developed residential and industrial centers may lose high recreation value as a result of torrential floods. The transformation of such a canyon bottom from a wooded, shady, vegetation-covered glen, to a barren waste of rocks and boulders, is a definite loss to society. Hikers, picnickers, and others seeking outdoor recreation do not gain as much pleasure from the use of an area so ravished. Although the actual number of people using the canyon may not be materially reduced, the pleasure and value to the user are less. If a correct analysis is to be made such flood losses must be given consideration.

The loss of a home and land by people who have given years of their life to their building is usually much greater than any factor commonly applied to the assessor's figures. The writer is familiar with cases in which people have spent several times the market value of their property repairing damage done by a single flood. In one case, about $40,000 was spent on replacing soil, trees, roads, and stream channel on a piece of property that could not be sold on the open market for $15,000. The writer is familiar with many other cases in which the individual cannot replace damage that was done by floods, but goes on year after year feeling a hurt in his soul each time he looks at the spot where the great oak once stood. This is a value that is not customarily included in flood loss. Sentimental values such as this are essential to human happiness and well being.

Other items exist for which it has been impossible to assign values. Loss of human life as well as loss of wild life is not usually considered in evaluating flood-control measures. Many streams in Southern California have been made useless for fishing as a result of floods.

---

[13] "Transient Flood Peaks," by Henry B. Lynch, *Transactions*, Am. Soc. C. E, Vol. 106 (1941), p. 199 (published in *Proceedings* in November, 1939).

In the economic analysis of a proposed flood-control program all benefits that will accrue to the proposed measures must be considered and evaluated if the results are to show correct justification. In light of the many indefinite items that combine to make up most studies, such as hydrology, damage relationships, etc., it does not appear to the writer to be such a far step to the monetary evaluation of intangible items such as the aforementioned. Widespread questionnaires, designed and analyzed by competent psychologists, could probably answer, with reasonable accuracy, the question regarding the loss of recreation value. A factor relationship might be developed between measurable and immeasurable benefits by a detailed study by competent technicians in various types of areas. Where measurable values are large, immeasurable values will usually also be large.

It appears to the writer that if flood-control expenditures are to be based on economic justification it will be necessary to set up "yardsticks" of evaluation for all items involved. When this is done in a consistent and uniform manner it will be a step toward the elimination of pressure-group flood-control expenditures. The "cards will be face up on the table" where every one can see the "winning hand." This will be particularly important during the coming years when flood-control projects will be in the foreground for taking up the slack of unemployment resulting from the reduction of the war industry.

Hyman J. Fine,[14] Assoc. M. Am. Soc. C. E.—The importance of the paper by Mr. Foster is readily realized by the fact that the justification for the millions of dollars spent annually on flood-protection projects must be based on a study of the seriousness and extent of the flood problem and on a comparison of the annual charges of the proposed projects with the annual benefits to be derived from them.

As stated in the paper, the average annual flood loss for a particular reach of river is based on: (*a*) The frequency curve for the control gage in the vicinity of the area under study; and (*b*) the stage-damage curve.

Frequency Curves.—On certain streams the available record of flood heights is not sufficiently complete for the preparation of reasonably accurate frequency curves. In many instances, recourse must be made to the flood data available for adjoining watersheds. Furthermore, frequency curves derived by equally acceptable methods of procedure may indicate a variation in the probability of flood stages.

The modified frequency graph for a certain section of a stream, wherein the floods are reduced by tributary storage reservoirs, depends on the flood routing studies which indicate the effect of such tributary regulation on the main stream flows. Such studies are usually complicated by the lack of adequate hydrological data of past storms for floods of varying magnitude.

The aforementioned factors indicate the importance of extensive hydrological research prior to the preparation of the required frequency curves.

---

[14] Associate Engr., U. S. Engr. Office, Norfolk, Va.

Stage-Damage Curve.—Mr. Foster properly emphasizes the necessity for exercising considerable judgment in the compilation of the data required for the stage-damage curve. In general, reliable information relative to the monetary losses from past floods is not readily obtained unless the floods are of recent occurrence. Furthermore, the establishment of a stage-damage curve, which is accurate throughout the range of probable flood heights, usually requires estimates of the losses for floods higher and lower than those that have occurred recently.

The three classes of property that generally constitute the major part of the damage appraisals to be made in urban areas are large industrial developments, small commercial establishments, and residential property. Large industrial establishments must be covered by separate interviews, and the plant engineer and manager are usually able to furnish the damage data required. In the case of the small commercial establishments or residences, it may be difficult to ascertain the future flood damages to the structures or improvements therein from the owners or representatives inasmuch as these people usually do not have sufficient knowledge of the cost of repairs. Such information can be obtained more readily from other sources.

As an example, Table 3 illustrates the collection of flood-damage data for a small commercial concern. The damage to the stock has been obtained from the proprietor who is thoroughly capable of furnishing such information. One important factor to take into consideration in estimating the stock damage is the time of flood warning available to the community, wherein this concern is located, so that the owner may raise his stock to a height higher than the crest of the anticipated flood. Damages to structures and improvements have been obtained from a curve indicating the cost of repairing floors, walls, plaster, fixtures, heating system, refrigerators, windows, doors, etc., for various heights of flooding. This latter curve is based on data furnished by contractors who perform such work. The repair costs should be reduced by a depreciation factor to determine the actual flood loss to the business establishment.

TABLE 3.—Appraisal of Flood Damages in Zone 1, Roanoke, Va., for the October, 1937, Flood and for Probable Floods Above and Below the 1937 Stage

(Mr. John R. Scott, Owner, Gille Clothing Co., 601 Chestnut Street, Roanoke, Va. [Left Bank of Stream])

Item of damage	Feet Above or Below the 1937 Stage:[a]									
	−8[b]	−6	−4[c]	−2	0	+2	+4	+6[d]	+8	+10
Direct Damage										
Structure and improvements			0	100	300	500	600	700	1,000	1,100
Machinery			0	50	200	350	350	350	600	700
Stock				0	400	600	600	600	1,200	1,500
Miscellaneous										
Total			0	150	900	1,450	1,550	1,650	2,800	3,300
Total indirect damage			0	100	300	440	500	580	1,120	1,320

[a] Elevation of 1937 stage in vicinity of establishment is 862.5 ft above mean sea level. [b] Ground. [c] First floor. [d] Second floor.

The indirect loss is expressed by the following formula:

$$\text{Indirect loss} = N\,S\,P \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which: N = number of days the establishment must be closed due to evacuation and rehabilitation following the flood; S = average daily sales lost during the flood period; and P = average gross markup per dollar of sale (including overhead, labor, and profit). A curve indicating the number of days of shutdown and rehabilitation for small business concerns can usually be established from actual flood data and from information furnished by contractors relative to time involved for repairs, etc. The average daily sales and the average gross markup can be obtained readily from the various business establishments affected by floods.

Agricultural Losses.—With reference to the method of deriving agricultural losses explained in the paper, it is believed that one additional item, which may be referred to as the inundation factor, should be taken into consideration and listed as item (*h*). This factor is based on the best available damage data for past floods of varying stages and may be expressed as follows: Inundation factor (for a flood of certain magnitude occurring in a particular month) $= \dfrac{\text{actual crop loss per acre}}{\text{maximum possible crop loss per acre for that month}}$. The total crop loss resulting from a flood of certain magnitude can now be expressed by

$$\text{Crop loss} = I\,(A\,C_1\,S_1\,L_1 + A\,C_2\,S_2\,L_2 + A\,C_3\,S_3\,L_3 + \cdots) \ldots\ldots (3)$$

in which: A = total cultivated area inundated; C = percentage of cultivated area in a certain crop; S = sales value of that crop per acre; L = maximum possible crop loss in the month that the flood occurred, in percentage of the sales value; and I = inundation factor. The $(S\,L)$-value would be obtained from a graph similar to that in Fig. 4.

If the inundation factor is taken into consideration, the crop loss value of $12.62 shown in Table 2 would not remain a constant for all stages. Depending on the topography of the area inundated, the crop loss would probably be a minimum at the lower stages, would gradually increase to a maximum at the medium stages, and then would remain at a maximum or possibly reduce slightly at the higher stages.

Annual Benefits Attributable to Local Protection.—Local protection improvements will usually eliminate all the losses caused by inundation up to the stage at which the flood-prevention structures are overtopped. Floods higher than those against which protection have heen provided have a certain probability of occurrence within the life of the protection works and may destroy or impair the usefulness of these structures. Therefore, it is logical to deduct, from the annual benefits, the incremental annual damages caused by such floods over what they would normally have caused without the construction of the flood prevention works.

Standardization of Data.—It is believed desirable to standardize on certain of the data required for a flood study. Stage-damage curves above first-floor levels for certain types of property, monthly crop-loss graphs, and other similar data, if available in standard form, would obviate the necessity of extensive studies for the preparation of such graphs.

Mr. Foster's paper is a distinct contribution toward the determination of the average annual losses resulting from floods and the benefits to be derived from flood-prevention structures.

Otto F. Buzhardt,[15] **Esq.**—A clear picture of the economics of flood control is presented in this paper. One point of special interest is the emphasis placed on indirect and unique losses and damages. It is usually a relatively simple matter to estimate physical flood losses or damages, but to evaluate indirect losses properly is often more difficult. These losses often exceed direct damages.

As Mr. Foster stated, stage-area and stage-damage curves may be derived through the use of information obtained through flood damage surveys. As a matter of fact, all estimations of flood damages and flood-control benefits depend primarily on field surveys of the flooded areas. When used in conjunction with the record of a conveniently located gage, areas and damages other than to crops may be determined readily for any stage. Typical examples of these curves are given in the following:

Fig. 6(*a*) shows the areas flooded, subdivided into cleared and total areas for respective gage heights. It will be noted that the cleared area usually begins well above bankfull stage because of the high frequency of overflow at the lower elevations. Naturally, under varying conditions, the areas that were inundated for a certain gage height may not be precisely the same but in general the difference will compensate.

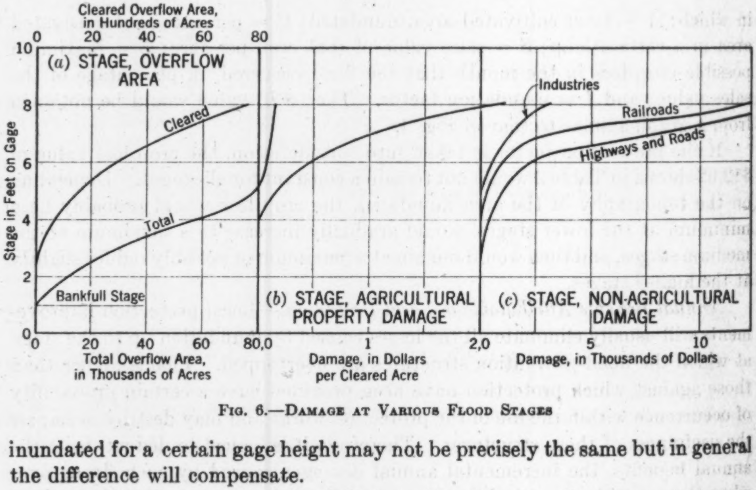

Fig. 6.—Damage at Various Flood Stages

The author asserts correctly that agricultural losses, other than crops, may be treated as urban losses, but it is logical to place damages of this kind on a per-cleared-acre basis (see Fig. 6(*b*)) since the types and extent of improvements primarily depend upon the cleared farm area. Usually these curves have a tendency to flatten out for higher stages due to the fact that improvements are located on higher parts of the flood plains. Mr. Foster has a good point in that, as a matter of conservatism, the maximum estimated damage for any property-value curve should be limited to that for which an actual computation has been made.

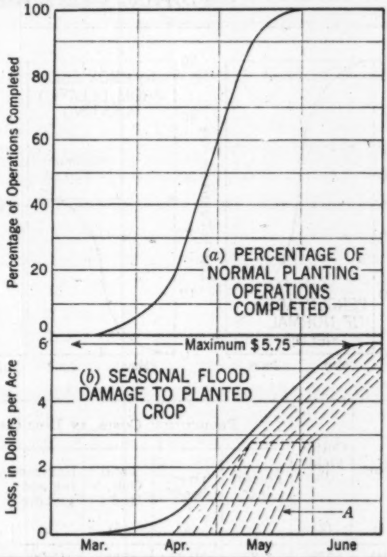
---

[15] U. S. Engr. Office, Vicksburg, Miss.

Stage-Nonagricultural Property Damages.—In order to construct a curve such as the stage-damage curve for Lawrence, Mass., damages such as those of Fig. 6(*c*) must first be ascertained. It is important to note Mr. Foster's explanation that the composite curve is of direct damages. Since indirect damages depend on factors other than stage, their values may not be a part of this or similar curves.

TABLE 4.—Derivation of Factors Used in Plotting Curve for Damages to Prepared Ground and Planted Crop

First date of flood	Preparing and Planting		Other Operations		Total damages
	% completed	Loss per acre	% completed	Loss per acre	
March 15	0	0.00	0	0.00	0.00
April 1	6	0.17	0	0.00	0.17
April 15	20	0.55	0	0.00	0.55
May 1	63	1.73	6	0.18	1.91
May 15	94	2.58	20	0.60	3.18
June 1	100	2.75	63	1.80	4.55
June 15	100	2.75	94	2.82	5.57
July 1	100	2.75	100	3.00	5.75



The author has summed up very neatly the data needed for the construction of crop curves, but since agricultural damages in some parts of the United States constitute the greater part of losses, it is believed that a more detailed explanation of the derivation of these curves is needed. Accurate estimates of crop losses are difficult to compute because of varying types of farming and crop distribution. Topography, as well as the sectional locality, determines the type of equipment used on farms, with a resulting difference in production costs. For this reason the basic information used in the following curves must apply to a specific area, but it is believed that the principle may be applied to a crop loss in any locality. Although the areas encountered support a variety of crops with a wide range in gross value of yields, curves relating to cotton crop damages are used for illustrative purposes.

Curve (*a*) in Table 4 shows the average first date (March 15) that cotton will be planted, with normal planting variations between these dates. This curve is considered with normal conditions only and is an integral part of curve (*b*), Table 4.

As Mr. Foster states, it is assumed that crops are destroyed when lands are flooded, regardless of the depth of water; therefore, the season of flooding is the governing factor in estimating crop losses. Curve (*b*), Table 4, the planted crop damage curve, is designed to show the accumulated expense incurred in planting and cultivating one acre of cotton. These values are referred to days of the year in order that planted crop damages may be obtained for any day on which an overflow may occur. Should a flood destroy a crop between March 15 and July 1, the resulting damage would be the amount corresponding to

[a] From curve (*a*). [b] Lint. [c] Includes planting, cultivating, and poisoning. [d] Includes work stock care. [e] Col. 9 minus 100% potential loss ($5.88), to be used in plotting curve (*b*).

the date of flooding. If this flood occurred at such a date that reasonable return could not be expected from a replanted crop, then floods subsequent to that date would naturally not damage crops below the elevation of the previous flood. In general, season permitting, crops are replanted within approximately ten days after lands are free from flood waters, the cost being almost equal to that of the first planting. As the season progresses, the speed of replanting operations is increased as shown by the broken lines "*A*" of curve (*b*)(Table 4). In estimations for a series of floods, the damages to a replanted crop are indicated by lines "*A*," the initial point falling ten days after the preceding flood. Consideration has been taken of the fact that flood water will gradually recede to bankfull stage, and it is assumed that a farmer will plant from the higher to lower elevations.

Curve (*a*), Table 5, shows the decline of production with respect to dates of late crop planting. This curve is used in deriving factors for curve (*b*), Table 5, "seasonal value of crop loss from delayed planting."

Crops destroyed by floods and planted after the average date of April 30 are usually reduced in production value. It is logical that a farmer will not continue replanting to a date beyond which his return is less than his cost of overhead and work stock care plus his normal net gain. Curve (*b*), Table 5, shows the rate of decline in production value. Curve (*c*), Table 5, "crop losses during harvest season," shows values of the crop from the time the crop is "laid by" through the harvest season. The maximum value shown in the curve is the sum of maximum values found in curves (*b*), Tables 4 and 5. When these curves, ((*b*), Table 4; and (*b*) and (*c*), Table 5) are combined, a curve such as Fig. 4 of the paper will be the result.

Under the heading "Benefits from Flood Control" it should be stated that channel improvement is used for stage reduction, as are reservoirs. The stages are reduced through better drainage facilities and as a rule the duration of flooding will be shorter. The entire flood will be moved forward—the first day of flooding occurring possibly a day or more earlier than it would have in the unimproved channel and the last day of flooding will probably be several days earlier, depending, of course, on the individual flood.

Contrary to Mr. Foster's view, the writer believes that the total benefits derived from a flood-control project should be: (1) Flood damages prevented, through protection, plus an increase to allow for future development of the area considered, without protection; (2) enhancement to lands already cleared; and (3) enhancement to woodland to be cleared. Some areas are subject to frequent flooding and, as a result, rich alluvial deposits have been built up. As a matter of fact, some farmers find this land so fertile that crops are planted in spots that are not above a three-year flood frequency. These are unusual cases, of course, and should the land be placed on the market for sale it would be found to have little value. Land values in these areas increase, however, as the elevation increases and the flood frequency decreases. It has been found through field investigation of protected areas, similar to those mentioned herein, that land values will be increased by improved flood conditions. This is due to the probability of increase in the productivity of the land through the use of more economical or intensive cultivation methods and rotation of crops.

In estimating the increased value of cleared land on the basis of increased productivity, the lands, under existing conditions, are analyzed to determine the average annual acre cost and income within the area considered. The comparison of these estimates with corresponding values representative of adjacent areas, not subject to frequent overflows, indicates the annual cleared land value to be expected by reason of flood control. If possible, it is preferable to compare the area under consideration with lands already protected by works similar to those proposed, rather than with lands above flood plains where values are dependent upon conditions other than flooding. Since the value of agricultural land varies, in general, according to its productivity or net income, comparison of values before and after protection is indicative of the annual increased land values. This value is exclusive of flood damages prevented.

Annual increased value of woodland, afforded protection, depends primarily upon its value as potential cultivatable land. Flood damages in wooded areas are usually negligible, and the wooded areas receiving benefits through flood control are restricted largely to those areas which might be suitable or desired for crop lands. Generally, parts of wooded areas to be protected are unsuitable for clearing without considerable expenditures for drainage improvement. Certain areas would be retained as timber or woodland for purposes other than crop production. Therefore, the amount of ultimate clearing to be expected in an area, as a result of flood control, may be estimated through comparison with other similar areas having essentially the same degree of protection as proposed for the area considered.

Remembering Mr. Foster's warning that values vary with elevation, for illustrative purposes it will be assumed that lands, in an area under discussion, average $25 per acre in value. Also, it will be assumed that the average gross value of crops on these cleared lands is equal to approximately 50% of the capital value of land at $12.50 per acre. Computed on a share rental basis, the net rental income will be approximately $2.50 or 10% of the capital value of land, from which interest on investment has not been deducted. To the annual gross value of crops ($12.50 per acre) may be added the annual value of damage to agricultural land that would be prevented by flood protection ($1.50 per acre for this particular area) the sum of which is the average annual gross value of crops given flood protection, or $14 per acre. Since the gross value of crops is equivalent to approximately 50% of the capital value of the land, a crop valued at $14 would be the yield of $28 land, the $3 per acre difference between $25 and $28 representing the capitalized value of flood damage prevented. However, it has been found that lands of the same type, and with the same degree of flood protection, have a value of $35 per acre. From this it is indicated that an average increase in capital value of $7 per acre would be obtained by flood protection beyond the value of flood-damage elimination, and it may be attributed to more favorable conditions. Based on the 10% expected on this cultivated land, an annual average increase in net return of $0.70 per acre on increased capital value of land, aside from that due to flood-damage elimination, would result.

In enhancement to lands to be cleared, it is assumed that the present value of unprotected woodland is $8 per acre, and that the average cost of clearing this land for farming purposes is approximately $15 per acre. From this, the capital value of the land when cleared must be in excess of $23 to give a profitable return. Should investigations prove that the ultimate value of land, when cleared, would be $33 per acre, the indication would be an increased capital value of $10 per acre if afforded protection. Based on an annual net return of 10%, the average annual net return in this case would be $1 per acre for the woodland to be cleared.

It should be remembered that the lands described herein are subject to frequent overflows, and values are not based on hysteria caused by an unusual flood, as was suggested by Mr. Foster in his description of the capital value method of land enhancement.

MALCOLM ELLIOTT,[16] **M. AM. SOC. C. E.**—The author correctly stresses the difficulties attending the use of depreciated property values in the evaluation of flood losses. In first place among these difficulties is the uncertainty as to the rate of interest to use in computing the capitalized value of the annual flood losses. However, lest it be understood that this difficulty is avoided by computing losses on an annual basis, the writer desires to emphasize that, regardless of whether the capital-loss or annual-loss methods are used, the determination of economic desirability of any flood-protection project depends on the adoption of a suitable rate of interest. The question raised by the author—"What rate?"—will inevitably plague the analyst in any case.

The difficulty can be illustrated by an assumed example pertaining to a flood-menaced area of 10,000 acres of corn land:

Benefits:		
Average flood losses, per acre per annum		$ 5
Average annual flood loss (10,000 × 5)		50,000
Costs:		
Cost of protection works		600,000
Annual interest and amortization combined, say 5%	$30,000	
Annual maintenance, operation, and all other annual charges	10,000	
Total annual charges		$ 40,000
Ratio, $\frac{\text{Benefits}}{\text{Costs}} = \frac{50{,}000}{40{,}000} =$		1.25

Can one conclude from this favorable ratio that the project is economically desirable? The capital investment in this instance may be considered the sum of the initial cost, $600,000, and the capitalized cost of future maintenance and operation, say $200,000, or a total of $800,000. This is the equivalent of $80 per acre and if, as often may be the case, other lands, flood-free and of equal fertility, may be bought in the vicinity for from $75 to $100 per acre, an investment of $80 per acre for flood protection of the bottom lands would appear uneconomical.

---

[16] Col., Corps of Engrs., U. S. Army; Div. Engr., Upper Mississippi Val. Div., St. Louis, Mo.

The foregoing case is purely imaginary, yet there have been actual cases studied and reported in which, although the comparison of annual benefits and costs appears to justify the project, the capital investment seems out of proportion to the capitalized benefits. Why (as in this case) is it possible to arrive at two different answers according to whether one uses the annual or lump-sum method of analyzing costs and benefits? Obviously the uncertainty is due to the rate of interest adopted. The 5% used in this example, for combined interest and amortization, corresponds reasonably to the rate of interest the federal government pays for borrowed money and an assumed 50-yr life of the project. Manifestly, some other rate of interest must be used if the annual and lump-sum methods of analysis are to be brought into agreement. Again, what rate?

Perhaps there is a fallacy involved in crediting the entire value of flood damages to benefits. By so doing the engineer assumes in effect that, had the floods been prevented, the farmer would have gained his customary return, whereas in fact he might have lost the crop anyway by reason of other causes such as drought, insects, glutted market, etc. It is even conceivable that a flood could benefit him in some years by wiping out early in the year a crop which if saved from floods might later have been destroyed by other causes.

The writer has searched in vain for a formula that will determine whether or not a project is meritorious or in fact complies with the mandate of Congress in the Flood Control Act of 1936 that the "Federal Government should improve or participate in the improvement of navigable waters or their tributaries * * * for flood control purposes if the benefits to whomsoever they may accrue are in excess of the estimated costs * * *." Although the ratio of cost to benefit is ordinarily computed on an annual basis using customary interest rates, it is believed that the final determination cannot depend on this ratio alone. A comparison of the capitalized benefits must also be computed and compared with the total cost of the improvements (including capitalized maintenance and operation) before the engineer can be sure that the investment is a good one.

JOHN B. MCALEER,[17] JUN. AM. SOC. C. E., AND JOHN B. DRISKO,[18] ESQ.—Some of the basic concepts of flood losses are described in this most valuable paper. The author discusses benefits derived from the prevention of direct and indirect flood losses, on the basis of his experience. The method outlined cannot be applied indiscriminately, however, to each and every problem of flood protection. The evaluation of some types of benefit will require other methods. The author mentions some of these (for example, "social losses" and "diminution of capital value of real estate"), but does not include them. In some cases, there are intangible losses that are not included in the category of indirect losses, and there are benefits that do not spring directly from the elimination of a recorded loss. Proper evaluation of flood losses can be realized only by thorough consideration of the entire problem in a river basin coupled with detailed investigations and studies. Superficial studies usually result in partial or inconclusive results.

---

[17] Associate Engr., U. S. Engr. Office, Providence, R. I.

[18] Engr., U. S. Engr. Office, Providence, R. I.

The author defines wealth and value as related to flood losses, based upon the *Encyclopædia Britannica*.[2] He makes no practical application of these concepts, however, and under the heading, "Collection of Damage Data," overlooks the determination of the value of the property to be protected. A knowledge of property values is essential to a common-sense view of protection. Determination of property values is required for "evaluation by estimating depreciated property value," a method briefly touched upon by Mr. Foster as an alternative method. Although not suggested by the author, it should be noted that this method ("evaluation by estimating depreciated property value") may also be used to supplement the "annual loss method."

The purpose of this discussion is to bring out the practical application of value and wealth as (1) an approach to a method of rational determination of benefits beyond the method of the author, and (2) a "yardstick" for comparison with the cost of the protective works. The method to be discussed is an application of the approach referred to by Mr. Foster as "capital loss method." The discussion will attempt to clear the basic principles of valuation and increases in property value that result from flood protection—increases that are often quite independent of flood losses. A superficial study of the matter leads one to believe that such benefits are completely evaluated under the annual direct and indirect losses and benefits. The discussion citing the benefits of the Connecticut River Flood Control Plan is an example of this very common error.

Proceeding with the discussion of a rational method of determining losses and benefits, flood losses may be classified in three basic types: "direct," "indirect," and "intangible."

"Direct losses" are the physical damage to property and goods; the usual indexes are the costs of repair, replacement, temporary shifting of goods, and cleanup. Direct losses are caused by each individual flood.

The "average annual direct losses" may be determined by: (*a*) Summing up the total losses over a period of years and dividing by the period of record in years; or, (*b*) determining the average ordinate of a curve showing the relation between direct loss and the frequency. Such a curve is obtained by combining the stage-loss relation and the stage-frequency relation.

"Indirect losses" are the value or cost of the service, or the use lost or made necessary as a result of flood conditions. Losses of business, extra costs of rerouted transport, and other similar losses, both in the flooded area and remote from it, are all indirect losses. Indirect losses are caused by each flood.

The "average annual indirect losses" may be estimated as a proportion of annual direct losses, the proportion being indicated by investigations made for outstanding floods.

"Intangible losses" are the third type of loss. These losses are not susceptible of direct evaluation although they are sometimes of commanding importance. The intangible losses should be given separate statement and consideration. They are partly reflected in changes of property value and may often be evaluated from these changes. The total depreciation of property values as a result of floods reflects not only the capitalized direct and indirect losses, but also the lessened utility and other adverse effects of an intangible nature which determine the use, the value, and the future of property. These intangible losses may be evaluated as real losses of property value, and they are equal to the total depreciation minus the capitalized direct and indirect losses. They may be called "depreciation losses," as distinct from "total depreciation," and classed under a separate category. They are equivalent to a portion of the intangible losses. Recoverable depreciation losses are more practicably evaluated under equivalent benefits—that is, as "increases of property value," because the extent of recovery will vary with time of protection, general economic conditions, prosperity of the region, demand for such properties, and condition of repair and use.

Intangible losses—including life, health, social and economic security, mental and physical distress—are caused by an individual flood but are intensified by a succession of floods—that is, by the flood history of a river. The knowledge that a certain area is subject to flooding casts a blight upon that area; and this causes a decrease in value which is often far greater than represented by the direct and indirect losses. Areas flooded frequently never develop fully, unless they are protected; areas visited for the first time by a record flood may suffer enormous depreciation, especially if the area is flooded or threatened more than once within a brief span of years.

Losses of the third class, intangible losses, are not susceptible of evaluation on the basis of recurring stage, or frequency. These intangible losses are reflected in real losses in the value and utility of property. Protection from floods will restore the value of such property and increase its utility. The benefits to be derived from the restoration of such values may best be classed as increase of property value.

The benefits of flood protection may be classed, then, as (*a*) direct, (*b*) indirect, (*c*) increases of property value, and (*d*) intangible benefits. Benefits (*d*) cannot be measured in dollars but include such items as prevention of loss of life, promotion of general welfare, and social security of the population. The benefits to be derived from a flood-control program are estimated on the basis of recurring losses which will be prevented, and upon the potential increases of value that may result from rendering recognized flood zones free of danger or from restoring highly developed zones that have been severely damaged by one or more unprecedented floods.

Direct and indirect benefits (Benefits (*a*) and (*b*)) are represented by the reduction in recurring losses. Many experienced losses are non-recurring by reason of altered usage or abandonment, or because replacement is combined with a betterment which renders future loss impossible or less likely. Recurring losses become less with each successive major flood, since property gradually becomes adjusted to the greater flood experience. Also, as a zone becomes recognized as a flood-dangerous zone, new capital is no longer introduced and the area may become stunted.

Increases of property value (Benefit (*c*)) are based on the higher utility and value that will result from adequate flood protection, insuring freedom from the disturbing disruption of possible flooding and increasing the net annual value or income of the property. Since many increases of property value that result from flood protection simply reflect the capital value of the direct and indirect losses prevented, benefits in this third class must be limited to a separate increment in value. Where property reflects important intangible losses or where the utility and value of property have been forced recently to a lower level by record flood experiences, increases in property values result from restoration to full utility by flood protection. These are equivalent to the restoration of depreciation losses. Often, benefits will result also from the more productive use of idle or partly developed lands where development has been retarded by floods, depending on future demand for such properties. In evaluating the annual benefits due to increases in property value, each area and class of property presents a problem for individual analysis. The capitalized value of average annual direct and local indirect losses that have been experienced should be deducted where overlapping occurs.

After the benefits have been determined they are compared with the costs of protection. If benefits exceed costs, the project may have merit, but if benefits are less, the project is not economically justified.

A few examples will show the necessity for considering the value of the real estate in relation to the total value of the property to be protected:

Case (*a*).—Consider a lumberyard which is subject to frequent flooding, and suppose the annual cost of protection to be less than the annual value of the losses sustained. If the cost of protection is high compared with the value of land and buildings involved, however, the business should be moved to high ground and flood protection for this property should not be considered.

Case (*b*).—Consider a dwelling that is frequently flooded, and for which annual costs of protection are found to be less than the value of the losses. If the capital cost of flood protection is a large percentage of the value of the house (say, 50%), then protection of the property is not economically sound. Similar reasoning will apply to larger areas also. In certain cases where it is found that the justifiable cost of protection exceeds the value of the property Congress provides in the Flood Control Act of 1938, for evacuation of an area as an alternate to protection.

Case (*c*).—Compare two flood properties—one, a farm that is frequently flooded, and the second a hotel building that is rarely flooded. Although annual direct and indirect losses of the hotel are equal to those of the farm, it is evident that, were the owners of the property to be assessed for the cost of local protective works, the hotel management would be willing to pay more for protection than the farmer, simply because it has a much larger investment or value at stake. In this connection it is of interest to remark that in most cases where the cost of protective works has been borne by the community protected, assessments against the individual properties have been based upon a percentage of valuation or upon an increase in value rather than upon the damage-frequency relation.

Suppose the benefits do exceed costs. Then, is the project economically sound? Although the government finances most flood protection the project should be considered from a strictly economic point of view. Consider a group of business men viewing an investment, with costs to be assessed from the owners of property protected or the owner of an industrial plant considering protection of the plant against floods:

The cost of protection must bear a reasonable relation to (1) the total value or capital value of the property to be protected and (2) the value of real estate or fixed equipment which may not be relocated or moved out of flood danger. This is elementary. If either of these relations is high the project should be abandoned.

Consider the example of the lumberyard described in Case (*a*). Suppose protection is estimated to cost $30,000, whereas capitalized annual benefits amount to $35,000. Protection would appear reasonable because the total worth of the establishment amounts to, say, $200,000; but closer inspection reveals that land and buildings are worth only $33,000, and the remaining worth is represented by stock. It is unreasonable to spend $30,000 to protect a bad investment of $33,000. The business should be moved to a more favorable site.

It is evident that the economic limit of protection should be set at some fraction of the value of the property to be protected, possibly 25%, and some greater portion of the value of real estate. Expenditures for flood protection should be held far below these limits unless benefits greatly exceed the cost of protection.

Consideration should be given to alternates to protective works: (1) Evacuation of the flood area, (2) altered use and zoning for future construction, (3) flood warnings, and (4) insurance.

The method of determining benefits, including increases of value, as outlined in this discussion, has definite advantages. It combines the precision of estimating benefits by the "annual loss" or "summation method" with the completeness of the methods based on "capital loss" or "differential" method. It is possible to determine, rationally, the "intangible" benefits which bear no relation to the direct and indirect losses and sometimes overshadow them. The method is no less accurate than any estimate of the worth of an industrial plant. The method is far more accurate than a computation by the annual-loss method.

"Intangible benefits" based upon "depreciation losses" and representing increases of property value minus capitalized direct and indirect losses will vary in each locality and watershed and are generally found limited to densely populated growing urban and industrial areas or adjacent areas where development has been seriously retarded by floods. In areas that are retrogressing, in which there are idle mills, and in which industry and activity are shrinking rather than growing, properties become greatly depreciated by economic conditions and floods, but there can be little recovery of value. Even direct and indirect benefits in these areas based upon past experience represent an exaggeration. In agricultural areas benefits based upon direct and indirect losses are usually found to equal or exceed the total increase in value so that intangible benefits are zero.

Since September, 1938, flood-control investigations have been made by the Providence (R. I.) Engineer District on five rivers in the Providence District: The Blackstone, Pawtuxet, Thames, Connecticut, and Housatonic.

The principal industrial development along the Blackstone and Pawtuxet rivers has been textile, and these industries have not prospered in late years.

Property values in these valleys have undergone economic depreciation, and recent floods have caused no recoverable depreciation.

The situation in the Connecticut Valley is quite different. The valley as a whole has prospered and activity is expanding. The valley has suffered three major floods in recent years—the 1927 flood, greatest for some seventy years; the 1936 flood, the greatest of record; and the 1938 flood, the second greatest of record on the main river and the greatest of record on the down-river tributaries.

This rapid succession of three great floods, during an otherwise favorable economic period of the valley, has caused substantial depreciation, a major part of which will be restored (and in some cases already has been restored) by proper flood-control measures.

Benefits accruing to the approved Connecticut River comprehensive flood control project have been analyzed by the method outlined herein. Annual flood control benefits are as follows:

Direct	$1,170,800
Indirect	1,029,100
Increases of property value	1,940,200
Total	$4,140,100

Capitalized at 5%, this is about $83,000,000 excluding incidental benefits to existing water power, navigation, recreation and pollution betterment, and to National Defense value, and without allowing for inevitable general growth and development of the area in the next fifty years, the period used for amortization of the works in all economic studies. The cost of the approved project is approximately $71,000,000. The total value of the property protected is approximately $856,000,000, and the real estate totals $596,000,000. Hence, benefits exceed the cost by 17%, and the cost of the project amounts to only 8.3% of the value of the property protected.

The increases of property value occur almost exclusively in the highly developed urban and industrial areas of the lower Connecticut Valley, where complete protection is afforded by the combination of a well-distributed reservoir system and the local protective works—that is, Northampton, Holyoke, Chicopee, Springfield, and West Springfield, in Massachusetts, and Hartford, and East Hartford, Conn. In Hartford, annual flood losses are as follows:

Direct	$ 191,800
Indirect	186,000
Depreciation	1,192,000
Total	$ 1,569,800
Capitalized at 5%	$31,396,000

It will be noted that depreciation losses are large in relation to direct and indirect losses. This is partly a result of the high value of the flood area (nearly $400,000,000) and partly because a dike built before the initiation of the federal project furnished protection against a flood having a probable frequency of occurrence of once in about fifty years and thus eliminated 60% of the annual direct and indirect losses. Had these low dikes not existed, the annual direct and indirect losses would have been about $950,000, and the depreciation would have been correspondingly less. The dikes, which had been constructed by local agencies, were topped in 1927, 1936, and 1938 with disturbing effect on property values in the flood areas. The "intangible" losses as measured by real "depreciation losses" are large and form the major part of economic justification for the dikes and walls which are now under construction. Bearing in mind that the initial benefits of stage reduction are credited to the reservoir system, the remaining benefits based upon the annual loss method would not justify raising the dike in spite of the fact that Hartford was flooded three times in eleven years, and that direct and indirect losses in this period amounted to $19,000,000. By estimating increases in value a more nearly correct measure of the benefits is obtained.

The foregoing study was based on data obtained prior to 1939. Since that time much of the local protection has been completed. Experience has shown that the estimate of benefits was extremely conservative. In one large area in Hartford, land in the flood plane increased 300% in value before the dike protecting it was completed. A large municipal airport which was relocated at a field 5 miles from the center of Hartford after the 1936 flood was returned to its location in the city as soon as dike protection was completed. Expansion of housing and industrial plants within the flood area has progressed rapidly.

Hartford is typical of the other cities of the lower valley, although on a larger scale. Existing dikes at Northampton, Holyoke, Chicopee, Springfield, and West Springfield which afforded partial protection prevented many of the direct and indirect losses, which would otherwise have been experienced frequently.

In these communities, local protection works which could be justified by the annual direct and indirect benefits would be only half-measures, and would neither provide valuable flood protection nor promote any confidence in the value of the works. A true summation of benefits, however, including increases of property value which reflect the "intangible" benefits based principally on "depreciation losses," gives a more nearly complete determination of the real benefits, and justifies the construction of complete protection for these areas. Complete protection, in turn, insures the realization of the manifold benefits.

It is on such a sound basis that local works in the Connecticut Valley have been constructed, and even brief experience shows that anticipated results will be exceeded.

In conclusion, the economics of flood protection requires a thorough consideration of the entire problem in each river basin. A detailed determination of the valuation of the property to be protected is one essential part of such an analysis. In some river basins a thorough consideration of values will show the necessity of supplementing and extending the method outlined by the author to include benefits resulting from increases of property value. With this addition, the suggestions offered by the writer have more general application to river basins of varying character, and make possible a complete and rational evaluation of benefits. The result is a more accurate comparison of benefits with the cost of flood protection.

Edgar E. Foster,[19] **Assoc. M. Am. Soc. C. E.**—The discussion brought forth by the paper has been highly gratifying to the writer. The discussers generally have approached the problem of flood losses and benefits from protection from different angles and have illuminated or elaborated on many points.

The uncertainty of occurrences of floods and extent of damage has been noted by Professor Chandler. Variability and uncertainty attend every factor entering into the formation of a flood and the aggregate of losses caused thereby. It is for this reason that the writer prefers to approach the problem of flood frequency from the statistical standpoint and to consider the prospective losses as a risk or a hazard. The danger in appropriate seasons is always present for the exposed localities so that there is a continual flood risk just as there is a never-ending fire risk.

The case for conservative treatment of flood economics was well stated by Mr. Burdick. Because of the uncertainty and difficulty of estimating flood losses and benefits of protection, more than ordinary precautions should be taken in their calculation. With all due precautions to obtain fully justified benefits, it is still possible to include indirect and intangible benefits where they are plainly suffered.

On the other hand, E. L. Chandler believes that the principles enunciated in the paper are ultra-conservative in that allowance is not made for benefits to be obtained by protecting economic developments likely to be made after flood protection is achieved. All flood-control projects require individual study and treatment, and perhaps there may be individual cases in which benefits to development subsequent to protection may justify a project. Such cases would be recognized in the allowance of enhancement of land benefit of areas to be protected when it is manifest that the flood risk has been the sole or principal factor that has retarded development and where it would be reasonably certain that the area would be developed to the degree attained on adjacent land after the removal of that risk.

To allow the elimination of losses to prospective development would open the way to speculative benefits in an undesirable degree. Certain considerations militate against claiming as benefits for a flood-control project the elimination of losses of economic development resulting from that project. A conservative view of the benefits should be taken because of the uncertainty of the final estimates of eliminating the direct losses; the estimates of the indirect and intangible benefits are even more unreliable. The development of an area given protection usually depends on more factors than merely flood protection. The general economic conditions of the country and the demand for land in the particular area should be considered; these factors may easily prevent development regardless of complete protection. Furthermore, recognition should be made of the probability that damage by future floods may not be as large as in the past because of the development of accurate means of flood prediction. In recent years, the U. S. Weather Bureau has built an extensive organization for the purpose of flood warning.

---

[19] Head, Flood Control Section, U. S. Engr. Office, Omaha, Nebr.

Professor Barrows agrees that estimates of annual benefits obtained by flood-damage surveys should not be combined with estimates of capital loss based on a single flood. There seems to be no serious question that such procedure is fallacious. It is now prohibited in the U. S. Engineer Department under the existing Orders and Regulations.

Colonel Elliott advocates the use of a capital-loss method as well as the annual-loss; but it should be noted that the capital-loss method he favors is not based on the depreciation of property value caused by one severe flood, but is in reality a capitalization of the estimated annual losses. The question of interest rate arises in such capitalization. It appears to the writer that the rate to be used in this conversion should be comparable to that which may be received or expected by an entrepreneur as a return of a business rather than the interest rate on a good loan or government bond. A return on a business enterprise usually would be higher than a rate of interest paid by the government. It is to be noted, however, that Colonel Elliott does not advocate combining the results of the two methods of computing benefits but only a comparison.

Colonel Elliott states that the problem of interest rate is not avoided by using the annual-loss method. In this he is right, for the interest rate appears in all financial matters. However, when a rate of interest is used in an estimate of cost, it is in the same status as any other item of cost such as steel, concrete, or land: It can be estimated at the current or expected rates for appropriate loans.

The annual cost of a large project consists of diverse items—interest on investment, amortization, repairs and maintenance, and cost of operation. Only the first is a constant function of capital cost. Amortization varies with the assignable life of parts of the project; repairs, maintenance, and operation may vary with little regard to the capital costs, although the relationship may become close with few diverse elements and low-cost operation. It appears, therefore, that a comparison between costs and benefits can be made more satisfactorily on the annual basis.

Flood control is expensive, and protection can be given only where there is a definite well-defined need for it. For a number of reasons it would be advantageous to eliminate losses from forest and recreational areas such as are described by Mr. Amidon, but manifestly it is not economically feasible to eliminate widely scattered losses in mountainous areas. This limitation usually will preclude the necessity for computing benefits. Nevertheless, occasionally there will be a need to estimate benefits on small streams subject to the "cloudburst" type of storm which occurs with such rarity that few statistics are available for the methods outlined. Recourse must then be made to whatever method can be used to determine a reasonable and conservative answer.

Mr. Amidon describes an excellent example to illustrate the subjective value as distinguished from exchange value of property. The person who spent $40,000 on his place must have considered it worth that much to him, although the sale value was only $15,000: The difference, $25,000, must be considered the personal or subjective value. This appears to be an extreme instance, but undoubtedly there are many cases of smaller degree in any large flood. A different type of subjective value is illustrated in the loss of pleasure of picnickers in denuded valleys: If they will pay nothing for flood protection, the value of their pleasure must be considered small.

In homes or places of business there undoubtedly are many items which may have no market value but which still furnish valuable service and have some personal or subjective value to the owners. These goods, if damaged by a flood, must be replaced. Such losses, reported and used in a determination of annual losses, may account for a part of the discrepancy between the capitalized annual losses and estimated property values mentioned by Colonel Elliott.

Since the annual loss depends upon the frequency as well as the loss per flood, it is almost self-evident that careful study must be given to the hydrological aspects of the evaluation of flood losses. The writer is glad that Mr. Fine has emphasized this feature.

Mr. Fine has also given some additional information of the mechanics of the computation of annual losses. Table 3 is a useful step in compiling data for the construction of the stage-damage curves. Turning to Mr. Fine's statement of agricultural losses, however, it appears that the use of the average value of crop loss throughout the season would eliminate the use of the "inundation factor" for purposes of obtaining the average annual loss per acre.

Mr. Buzhardt has given considerably more details of the methods used in the Mississippi Valley for computing the average annual crop losses. Such losses constitute the principal type of losses in that region, and his discussion is of value for that reason. Where any one type of flood becomes predominant, it should be treated in considerable detail. In the broad, fertile, alluvial valleys of the Lower Mississippi River Basin, agriculture is the predominant industry and therefore agricultural flood losses there have been studied probably more extensively than elsewhere in the United States. For this reason, the additional details of the computations of agricultural flood losses are welcome.

In referring to agricultural losses other than of crops, Mr. Buzhardt states that stage-damage curves flatten out. When the stage is plotted on the ordinates and damages on the abscissas, the curve will approach some ordinate as an asymptote as the damages approach the probable total property value. The same situation would occur in any stage-damage curve, urban as well as rural, except that in the former the total property value within a given area may exceed the probable flood loss so greatly that the change in the direction of the curve is not reached by the maximum observed flood.

Mr. Buzhardt believes that the total benefits of protective works would be derived from: (1) Flood damages prevented, plus an allowance for future development without protection; (2) enhancement to lands already cleared; and (3) enhancement to woodland to be cleared.

Item (1), flood damages prevented, is taken to mean average annual flood loss. If the losses are to be estimated on the annual basis, it is agreed that this item is correct. Whether or not an allowance is made for future development should depend entirely upon the local conditions. The writer believes that, as a general rule, in the interest of conservatism, no allowance or very little allowance should be made for future development. Nevertheless, perhaps there are localities to which this general rule could not be applied, such as the existence of particularly important advantages of a site that would induce settlement despite a known flood hazard.

In item (3), there would be little or no annual losses, as Mr. Buzhardt states. The enhancement of value would be made possible because the land is made susceptible of higher development if protected and therefore would return a greater income. As stated by the writer under "Other Benefits from Flood Control," such increased values may be accepted as a benefit for protection if there is a reasonable certainty of utilization. The critical question in this case is whether or not the flood menace was the sole or principal cause of lack of development. If so, there is good reason to believe that the land would be developed if protected, and the increased value may be assumed as a benefit.

On the other hand, item (2), the enhancement of value of cleared land, appears to be an increase in land value brought about by the elimination of the annual flood losses. The correctness of this view is indicated by Mr. Buzhardt's statements: "Land values in these areas increase, however, as the elevation increases and the flood frequency decreases"; and again, "Since the value of agricultural land varies, in general, according to its productivity or net income, comparison of values before and after protection is indicative of the annual increased land values." These land values are taken as capital values as the word "annual" does not appear to change the general meaning. Since there are intermittent floods, the constant flood risk is recognized by buyer and seller alike, and the capital value of the land is decreased by an amount that is substantially a subjective capitalization of the annual flood losses, including the personal risk. The land enhancement of the cleared land, therefore, is simply a restoration of this capitalized loss. The writer firmly believes that this land enhancement should not, therefore, be combined in any manner with the annual losses to obtain a total benefit.

The purpose of including the definition of wealth was to lay the groundwork for the summation of total wealth, the Community Property Account and, in conjunction with the definition of "value," to set a standard by which the personal risk could be measured. By these definitions it was hoped that duplications of losses and benefits could be eliminated.

Since the provision of flood protection is an economic matter and since the costs are measured in dollars, the benefits must be reduced to the same basis in order to make a comparison. The loss of human life may be serious, but it is not possible to evaluate it in terms of money loss to the community without making many more or less arbitrary assumptions. Fundamentally, the value of human life is what the individual makes it in terms of associations with his fellow men rather than in dollars. It will be seen readily that the value will vary greatly among individuals; the possible loss is a personal risk that can be gaged only by that which the individual will pay to prevent it.

The economic losses caused by a flood may be classified in many ways, but the writer believes that, aside from the loss of life, the two classes are sufficient for all purposes, namely, direct and indirect. This indirect category would also include all intangibles listed by Messrs. McAleer and Drisko which have a monetary value.

These so-called intangibles generally constitute the controversial items of flood loss. The fact that they are difficult to define or evaluate should be sufficient reason to regard them with suspicion and treat them conservatively. It is easy to make claims for extensive losses on such grounds but every claim should be examined for a market value or a prospect that the sufferer would pay good money to escape a repetition of the loss. Life and health will have a definite value to the individual, but the average person is not likely to pay much to eliminate danger to either once in 50 or 100 years.

Social and economic security are matters of every-day concern; there is only a relative difference in these items during floods except as the latter affect property adversely. During high water there is undoubtedly physical and mental distress among the flood victims; but what market value can be placed on those factors except that which the sufferers will pay to escape? On the other hand, if one can ascribe a value to such items as mental distress, why not credit floods with an entertainment benefit obtained by the many, untouched by the flood, who spend days in viewing the novel and interesting scenes? The writer has heard of floods in places where the inhabitants got a jug of corn liquor and really enjoyed themselves.

The utility of property is not, in general, intangible in the sense that it has no economic value. All commercial and industrial property exists for one purpose—business—and the object of business is profit. Between floods, business proceeds as usual. There is no reduction of utility because of floods except at the time of occurrence and, therefore, no loss of profit except when flood damage is chargeable against income. Therefore, the loss of utility is measured in loss of income. Noncommercial property such as residences, churches, schools, parks, and libraries present a somewhat, but not fundamentally, different picture. The loss of utility is confined to the period of high water and repairs; the utility is obtained by direct use rather than through income; there is a greater personal risk involved; the losses constitute increased cost of maintenance rather than charges against income. Except for the personal risk, the loss of utility can be measured by the rehabilitation and loss of service or rents.

Regardless of the class or kind of property, the owner can suffer only the losses caused by a flood during his period of ownership, and suffer those as they occur. He will not suffer the loss of capital value until he sells; the known flood risk, of course, will cause a reduction of property value; but after the owner has sold, and accepted his capital loss, he will not be liable for the periodic flood damage. Any given individual cannot suffer both losses and therefore the community cannot suffer the total of both, since community wealth is simply the aggregate of the individuals' wealth.

Messrs. McAleer and Drisko present what they term a more accurate method of determining flood losses. Essentially the method consists of a determination of the capital losses of depreciation of property value which result from floods and a determination of the annual direct and indirect loss. The annual direct and indirect loss is capitalized and the result deducted from the total depreciation loss; some rate of interest is applied to the remainder and the result is called the annual intangible loss.

It can be seen readily that the determination of the total depreciated property loss is the controlling factor; since the total annual loss includes the intangible, the determination of the direct and indirect annual losses is merely a means of allocating portions of the total losses to those categories, the portions being fixed to a large extent by the rate of interest used in capitalization. This method is open to all the objections of basing the economics of flood control on one flood: It does not give adequate consideration to small floods; the frequency of the one flood may be such that the observed damage does not fairly represent the expected average over a period of years; the hysteria following a major disaster is probably a large contributing factor in depreciating property values. Messrs. McAleer and Drisko state that their "method is far more accurate than a computation by the annual-loss method." This statement is questionable in view of the uncertainties introduced and the necessarily arbitrary selection of interest rates.

Occasionally, losses in a community are claimed because industrial or commercial units move from a locality, town, or city that is subject to floods or because a known flood menace causes business organizations to locate elsewhere. In this matter, the interests of the community and state or nation diverge. The loss of a business unit will undoubtedly have an adverse effect on the community because some employees are likely to be left without employment and the community loses a source of tax revenue; but such losses do not accrue to the state or country as long as the business relocates within its boundaries. There will be some expense in moving but this should be chargeable to the savings in flood losses. The total wealth or income of the state or country is the aggregate of the wealth or income of individuals, and it is not affected by the location of the individuals within its boundary. For this reason, an intangible loss should not be claimed because of relocation or lack of industrial development of a flood-menaced area, when the cost of flood protection is to be borne by the United States.

Before closing this discussion, another aspect of the economics of floods must be mentioned. Through correspondence, R. M. McCrone, M. Am. Soc. C. E., raised the question of direct flood benefits. In a humid climate, such benefits are scarcely conceivable; but in the sub-humid and semi-arid regions of the West where dry-farming is practiced, real benefits are obtained from the smaller overflows which provide needed irrigation water. In one instance that came to the writer's attention, a net benefit of $6,000 was reported from one spring flood that covered an extensive area of hay land. This situation is another indication that each flooded locality provides a separate problem and should be studied in the light of sound and conservative basic economic principles.

WIND STRESS ANALYSIS BY THE *K*-PERCENTAGE METHOD

By F. P. Witmer,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. M. Goodrich, Francis L. Castleman, Jr., Clyde T. Morris, Otto Gottschalk, and F. P. Witmer.

Synopsis

The purpose in preparing this paper was twofold:

(1) To describe in detail a procedure for applying the *K*-percentage method of wind stress analysis which was presented[2] in 1939, in order to facilitate its practical utilization; and

(2) To present a method of design, using the aforementioned principles, but with the assumption that vertical wind reactions and direct wind stresses in columns must be in accordance with the cantilever relation, thus eliminating all secondary moments due to change in length of columns under their direct wind stresses.

Present Methods of Design

In the analysis and design of a building bent of the usual type, having girders framed between columns, with small connections designed to resist pure bending, the engineer is confronted at the outset with two alternative methods of procedure, for the determination of wind stresses:

(1) An "approximate" method, in which the distribution of vertical wind shear across the bent is assumed to occur in some arbitrarily assigned relation, without consideration of the elastic behavior of the various members of the bent; and

(2) One of the so-called "exact" methods, in which the elastic action is considered in a more or less accurate theoretical manner.

The approximate methods are much more readily and quickly performed, and, for buildings of usual proportions, are quite satisfactory, both practically and economically, although their resultant stresses may be considerably in error. However, they ignore the secondary bending moments resulting from

change in length of columns under direct wind stresses and, for extreme proportions of height to width of bent, these moments may attain serious magnitude.

The exact methods give correct values for primary wind stresses, but, as usually applied, they also ignore these secondary moments. In one case, however, that of the "Spurr method,"[3] this procedure is entirely justified, because, since the bent is assumed to act as a cantilever fixed at the base, and is carefully designed elastically upon this premise, all joints in each floor will remain in a plane under wind load, and these secondary moments, therefore, will be non-existent.

By any method other than the Spurr method, it is thus seen that these effects of column axial wind distortion are habitually neglected, unless a separate additional analysis of them is made by some more or less laborious process.

The principal approximate methods in use have been two—the "Portal Method" and the "Cantilever Method"—both described[4] by Robins Fleming in 1913. The portal method assumes that vertical wind reactions and direct wind stresses for all interior columns are equal to zero. The cantilever method assumes the direct-wind unit stresses in columns to be proportional to the distance of the column from the neutral axis of the bent. Neither method takes into account the fact that these particular relations of reactions and stresses cannot exist unless the relative sizes of columns and girders are such as to develop them by elastic action. The reactions assumed in the portal method are theoretically correct for primary wind moments if all sizes have been computed from vertical floor loads alone, assuming discontinuous girders, and also assuming: That the floor load is constant throughout any floor; that girders in any floor are of the same depth throughout; and that column areas are always proportional to their moments of inertia.[5] If these assumptions are not made, the portal method is only approximately correct, the degree of accuracy depending upon the degree of departure from these assumptions. The cantilever method can only give correct results if the relation of sizes happens to be such as to develop the assumed reactions and direct column stresses when the bent distorts elastically. This condition will obviously be only of accidental occurrence.

Of the so-called "exact" methods, the "slope deflection method," introduced in 1915 by W. M. Wilson and G. A. Maney,[6] Members, Am. Soc. C. E., and the method of end-moment distribution, presented by Hardy Cross,[7] M. Am. Soc. C. E., are the most outstanding. Each will produce a correct analysis of primary wind moments for a bent whose members are of any assumed size. Both are laborious, that of Professor Cross being far more practical in the case of bents many stories high. Neither method, as before stated, takes account of secondary bendings from column, axial, wind distortion, without an additional analysis made for this purpose.

time-consuming. In the present paper a new method is presented which is both rapid and convenient, at the same time insuring practical agreement with the cantilever relation of column, vertical, wind reactions which is necessary to justify ignoring the secondary wind effects. The proposed method is based upon the "method of K-percentages" first reported in 1939,[2] and particularly utilizes the relation[8] that ΣI varies as $V_g\, L_g^2$, in which ΣI = approximate sum of moments of inertia of all girders in a bay; V_g = relative vertical wind shear in the bay as determined from relative wind reactions required by the cantilever theory; and L_g = length of girder in the bay.

A bent of assumed dimensions, carrying a specified floor load and wind load, was designed by the proposed method. For this purpose, a bent of three bays was assumed, the outer ones each being 20 ft wide and the inner one 30 ft wide (see Fig. 1). Ten equal stories of 20-ft height were assumed and bents were assumed to be 15 ft apart. Floor loads (inclusive of all dead load) were assumed equal to 200 lb per sq ft for all floors and a horizontal wind force of 33⅓ lb per sq ft was used. Assuming a parapet 10 ft high produced a uniform wind force of 10 kips at each floor (1 kip equals 1 "kilo-pound," or 1,000 lb), which was adopted for convenience in calculations.

A unit fiber stress of 18 kips per sq in. was used for girders and 12 kips per sq in. in compression for all columns, regardless of their slenderness ratios. At the ends of columns, however, where no buckling need be considered, 18 kips per sq in. were allowed for compression, inclusive of wind bending stress. One third of the vertical load stress was deducted when wind stress was included, for both girders and columns; and for girders, the end moment for vertical loads was taken at two thirds that at the center of a simple span of the same length.

The first step is to compute all girder moments and column stresses from the vertical floor load of 200 lb per sq ft, assuming girders to be non-continuous. The tentative column areas of first-story columns for this stress are as follows —

Column C_O: $300 \div 12 = 25.0$ sq in. required

Use 12-in., 85-lb H = 24.98 in.^{2}

Column C_I: $750 \div 12 = 62.5$ sq in. required

Use 14-in., 215-lb H = 63.21 sq in.

The maximum moments, in kip-inches, at the centers of all girders are as follows:

Location	Girders G_O	Girders G_I
At center	1,800	4,050
At ends	1,200	2,700

The column stresses due to vertical loads are given in Table 1.

TABLE 1.—COLUMN STRESSES, IN KIPS PER SQUARE INCH, DUE TO VERTICAL LOADS

Column (see Fig. 1)	Floor No.:									
	1	2	3	4	5	6	7	8	9	
C_O	300	270	240	210	180	150	120	90	60	30
C_I	750	675	600	525	450	375	300	225	150	75

---

[8] *Proceedings*, Am. Soc. C. E., June, 1939, p. 977.

Assume that the unit stresses in columns are proportional to their distance from the neutral axis of the bent, which, in this case, is at the center. Then, if A_O and A_I are the tentative areas of the outer and inner first-story columns respectively, and the vertical wind reaction R_O at the outer column is taken at unity, the inner-column wind reaction will be (see Fig. 1): $R_I = \frac{15}{35} \times \frac{A_I}{A_O} = \frac{15}{35} \times \frac{63.21}{24.98} = 1.09$. If $R_O = 1.0$, this also equals the vertical wind shear V_O in the outer bay. Then the vertical wind shear in the inner bay will be $V_I = R_O + R_I = 1.0 + 1.09 = 2.09$.

Hence, if I_O equals the moment of inertia of the outer girder in any floor, that of inner girder in the same floor will be $I_I = I_O \times 2.09 \times \frac{30^2}{20^2} = 4.70$.

Thus the moment of inertia of any inner girder should be equal to 4.70 times that of outer girder in the same floor in order to produce the cantilever relation of vertical wind reactions. This ratio will be subject to verification and possible change after the actual design of girders and columns for the inclusion of wind stress.

The next step is to compute wind moments in the girders, assuming vertical, column, wind, reactions and direct stresses in the various stories to be in the proportion of 1.0 and 1.09 for outer and inner columns respectively, and assuming all points of contraflexure at the mid-point of the member except first-story columns. For the latter it is better to assume the point of contraflexure at sixth tenths of the story height above the bottom. Each of the outer girder moments is taken as equal to the product of one half the girder length center to center of columns by the shear received from the column at its outer end. This shear equals the difference between outer column direct wind stresses above and below the floor in question.

The direct wind stress in the outer column of any story will be found by the following moment equation:

$$M = 70\, C_O + (1.09 \times 30)\, C_O = 102.7\, C_O \quad \ldots\ldots\ldots\ldots (1)$$

from which

$$C_O = \frac{M}{102.7} \quad \ldots\ldots\ldots\ldots (2)$$

In Eqs. 1 and 2, M equals the wind moment about the point of contraflexure of the column in the story in question and C_O is the stress in the outer column of this story.

It is not actually necessary to compute these wind moments.[9] The horizontal wind shears in all stories are always readily available and the difference between M_9 and M_{10}, for instance, in stories 9 and 10, will be

$$M_{10} - M_9 = \frac{H_9\, h_9}{2} + \frac{H_{10}\, h_{10}}{2} \quad \ldots\ldots\ldots\ldots (3)$$

in which H_9 and H_{10} are the story, horizontal, wind shears, and h_9 and h_{10} are the story heights. This relation is easily shown to be true. Hence, the wind moment in the outer girder of floor 9 (between stories 9 and 10) is equal to $\frac{1}{102.7}\left(\frac{H_9 h_9}{2} + \frac{H_{10} h_{10}}{2}\right) \times 10$. For the top girder, this moment becomes $\frac{1}{102.7}\left(\frac{H_{10} h_{10}}{2}\right) \times 10 = \frac{1}{102.7}(10 \times 10) \times 10 = +9.7$ kip-ft. For the ninth floor girder, it is $\frac{1}{102.7}(10 \times 10 + 20 \times 10) \times 10 + 29.2$ kip-ft and similarly for the other floors above the first floor. For the first story, the point of contraflexure being at six tenths of the story height above the base, or four tenths of this height below the floor, $M_1 - M_2 = \frac{H_2 h_2}{2} + H_1 \times 8$, from which the moment in the girder is $\frac{1}{102.7}\left(\frac{H_2 h_2}{2} + H_1 \times 8\right) \times 10 = \frac{1}{102.7}\left(90 \times \frac{20}{2} + 100 \times 8\right) \times 10 = +165.5$ kip-ft.

---

[9] *Proceedings*, Am. Soc. C. E., June, 1939, p. 980.

For inner girders, the moments will be equal to those for the corresponding outer girders, multiplied by $\frac{V_I}{V_O} \times \frac{15}{10}$, in which V_I and V_O are, respectively, the vertical wind shears in the inner and outer bays. As found before, if $V_O = 1.0$, $V_I = 2.09$. Hence, if M_O and M_I are moments in outer and inner girders, respectively, $M_I = M_O \times \frac{2.09}{1.0} \times \frac{15}{10}$. All inner girder moments are thus quickly found.

By the condition that $\Sigma M = 0$ at each joint, and working from the top of bent downward, column moments are all readily determined from the girder moments, except those at the bottom of the first story. Thus (in kip-ft):

Story		C_O
10		-9.7
9		$-(29.2 - 9.7) = -19.5$
: : :	etc.	: : :

For the bottom of the first-story columns, the total wind moment in the first story (that is, 100 × 20 ft = 2,000 kip-ft) is assumed divided among the four columns in proportion to their *K*-values, or, as all have the same length, in proportion to their moments of inertia. The tentative areas of C_O and C_I are, respectively, 24.98 sq in. and 63.21 sq in. Assuming these columns to be tentatively 12-in., 85-lb H ($I = 723.3$) and 14-in., 215-lb H ($I = 2{,}730.0$) these columns will have total moments of $\frac{2{,}000}{2 \times 3{,}453.3} \times 723.3 = 209.5$ kip-ft and $\frac{2{,}000}{2 \times 3{,}453.3} \times 2{,}730.0 = 790.7$ kip-ft, respectively. Deducting from these moments the moments previously found at the top of columns in first story, the base moments given in Fig. 1 are determined, this figure also giving the wind moments throughout, computed as described herein. Wind reactions in Fig. 1 are found as follows:

By taking moments about the contraflexure point in the first story, assumed to be 8 ft below the first floor,

$$R_O = \frac{(10 \times 10)\ (20\ \text{ft} \times 4.5 + 8\ \text{ft})}{102.7} = 95.42\ \text{kips}$$

and

$$R_I = R_O \times 1.09 = 104.0\ \text{kips}.$$

The total moment in the outer column of the first story was found to be 209.5 kip-ft. Hence, $H_O = \frac{209.5}{20} = 10.47$ kips.

$$\text{Similarly, } H_I = \frac{790.7}{20} = 39.53\ \text{kips}.$$

The corresponding location of points of contraflexure will be at distances above the base of $\frac{131{,}500}{10{,}470} = 12.56$ ft and $\frac{468{,}200}{39{,}530} = 11.84$ ft respectively, instead of sixth tenths of 20 ft = 12 ft as was assumed originally in computing wind moments.

The next step is to proportion columns and outer girders for vertical loads, or for vertical loads combined with wind stresses, whichever will require the greater section. Inner girders are then to be proportioned by making the moment of inertia of any girder, as nearly as practicable, equal to 4.70 times that of the outer girder in the same floor, unless its stress from vertical and wind loads requires a larger section. In the latter case the corresponding outer girder must be increased until its moment of inertia is equal to $\frac{1}{4.70}$ times that of the inner girder. In other words, the relation $I_I = 4.70\ I_O$ must be maintained in order to produce the assumed cantilever relation of wind reactions, while, at the same time, no girder or column may be of less section than is required by its own maximum stresses.

TABLE 2.—SIZES OF H-BEAMS AFTER PROPORTIONING FOR WIND AND VERTICAL LOADS

Floor or story	Columns		Girders	
	Outer (C_O)	Inner (C_I)	Outer (G_O)	Inner (G_I)
10	12 in., 32 lb	14 in., 58 lb	21 in., 59 lb	33 in., 125 lb
9	12 in., 32 lb	14 in., 58 lb	21 in., 59 lb	33 in., 125 lb
8	12 in , 45 lb	14 in., 111 lb	21 in., 59 lb	33 in., 125 lb
7	12 in., 45 lb	14 in., 111 lb	21 in., 59 lb	33 in., 125 lb
6	12 in., 58 lb	14 in., 158 lb	21 in., 59 lb	33 in., 125 lb
5	12 in., 58 lb	14 in., 158 lb	21 in., 59 lb	33 in., 125 lb
4	12 in., 79 lb	14 in., 211 lb	21 in., 68 lb	33 in., 132 lb
3	12 in., 79 lb	14 in., 211 lb	24 in., 74 lb	36 in., 160 lb
2	12 in., 85 lb	14 in., 237 lb	24 in., 74 lb	36 in., 160 lb
1	12 in., 85 lb[a]	14 in., 237 lb[b]	24 in., 74 lb	36 in., 160 lb

[a] With two plates, 9 in. by $\frac{7}{8}$ in. by 3 ft at bottom. [b] With two plates, 11 in. by $\frac{11}{16}$ in. by 4.0 ft at bottom.

In proportioning columns, the ratio of the moments of inertia in inner and outer columns should be maintained as nearly constant as practicable for the same reason as was stated in the case of girders. This condition, however, is not nearly so essential as is the proper relation of girder moments of inertia. The effect upon the wind-reaction ratio of a change in the relative size of girders is much more pronounced than is the effect of a similar change in columns.

Table 2 shows sizes of all members after proportioning them for vertical loads and wind. This operation, in some detail, is as follows:

Design of Outer Girders G_O, First Floor.—

Maximum moment at center = 1,800 kip-in. at 18 kips per sq in. = 100 (minimum section modulus required)

Maximum moment at end = 1,200 kip-in.
Less one third = 400 kip-in.

Net moment from vertical load = 800 kip-in.
Wind moment 165.5 kip-ft × 12 in. = 1,986 kip-in.

Total end moment = 2,786 kip-in.; at 18 kips per sq in. = 154.8 section modulus required

Use 24-in. 74-lb H (170.4 section modulus; $I = 2{,}033.8$)

A similar procedure is followed for each floor to determine the sizes shown in Table 2.

Design of Inner Girders G_I, First Floor.—

Maximum moment at center = 4,050 kip-in., at 18 kips per sq in. = 225 (minimum section modulus required)

Maximum moment at end = 2,700 kip-in.
Less one third = 900 kip-in.

Net moment from vertical load = 1,800 kip-in.
Wind moment 518.8 kip-ft × 12 in. = 6,225 kip-in.

Total end moment = 8,025 kip-in.; at 18 kips per sq in. = 445.8 section modulus required

A 33-in. 141-lb H (446.8 section modulus; $I = 7{,}442.2$) is sufficient for stress. However, the designer must consider the relative moments of inertia of girders G_O and G_I:

$$I \text{ of } G_O = 2{,}033.8\text{; hence, the required—}$$
$$I \text{ of } G_I = 2{,}033.8 \times 4.70 = 9{,}560 \text{ in.}^4$$

Therefore, for G_I, use a 36-in. 160-lb H ($I = 9{,}738.8$).

In a similar manner sizes for all inner girders are found, as given in Table 2.

Design of Outer Columns C_O, First Story.—

Vertical load = 300 kips, at 12 kips per sq in. = 25.0 sq in.
Less one third = 100 kips

Net vertical load = 200 kips

Wind Load (Top).—

78 kip-ft × 12 in. × $\frac{c}{r^2}$ = 200 ($c = 6.25$ in. and $r = 5.38$ in.)

Total at end = 400 kips, at 18 kips per sq in. = 22.2 sq in.
Use a 12-in. 85-lb H (24.98 sq in.; $I = 723.3$).

Wind Load (Bottom).—

131.5 kip-ft × 12 in. × $\frac{c}{r^2}$ = 343 kips
Net vertical load = 200 kips

Total at end = 543 kips, at 18 kips per sq in. = 30.2 sq in.
Use a 12-in. 85-lb H (24.98 sq in.), with two plates
9 in. by ⅜ in. by 3.0 ft = 6.75 (at base)

Total at base = 31.73 sq in.

Design of Outer Columns C_O, Second Story.—

Vertical load = 270 kips, at 12 kips per sq in. = 22.5 sq in.
Less one third = 90 kips

Net vertical load = 180 kips

Wind 87.5 kip-ft × 12 in. × $\frac{c}{r^2}$ = 227 kips ($c = 6.25$ in. and $r = 5.38$ in.)

Total at end = 407 kips, at 18 kips per sq in. = 22.6 sq in.
Use 12-in. 85-lb H (24.98 sq in.) for first and second stories.

Similarly sizes for other stories are obtained as given in Table 2.

Design of Inner Columns C_I, First Story.—

Vertical load = 750 kips, at 12 kips per sq in. = 62.5 sq in.
Less one third = 250 kips

Net vertical load = 500 kips

Wind Load (Top).—

322.5 kip-ft × 12 in. × $\frac{c}{r^2}$ = 709 kips ($c = 8.06$ in. and $r = 6.65$ in.)

Total at end = 1,209 kips, at 18 kips = 67.2 sq in.
Use a 14-in. 237-lb H (69.69 sq in.; $I = 3{,}080.9$ in.^{4}).

Wind Load (Bottom).—

468.2 kip-ft × 12 in. × $\frac{c}{r^2}$ = 1,024 kips
Net vertical load = 500 kips

Total at end = 1,524 kips, at 18 kips per sq in. = 84.8 sq in.
Use a 14-in. 237-lb H = 69.69 sq in.
Plus two plates, 11 by $\frac{11}{16}$ by 4.0 ft = 15.14 sq in. (at base)

Total at base = 84.83 sq in.

Second Story.—

Vertical load = 675 kips, at 12 kips per sq in. = 56.25 sq in.
Less one third = 225 kips

Net vertical load = 450 kips
Wind 361.8 kip-ft × 12 in. × $\frac{c}{r^2}$ = 793 kips

Total at end = 1,243 kips, at 18 kips per sq in. = 69.1 sq in.
Use 14-in. 237-lb H (69.69 sq in.) for the first and second stories.

Similarly, sizes are obtained for other stories, as given in Table 2.

All sizes having been determined, a check for the reaction ratio $\frac{R_I}{R_O}$ will now be made by the *K*-percentage method:

	Moments of inertia, *I*, for:	
Stories	C_O	C_I
1st and 2d	723.3	3,080.9
3d and 4th	663.0	2,671.4
5th and 6th	476.1	1,900.6
7th and 8th	350.8	1,266.5
9th and 10th	246.8	597.9
	2,460.0	9,517.3

Average I = 492.0 = 1,903.5
Average K = 24.6 = 95.17
Ratio $\frac{C_I}{C_O}$ = 3.87

Although this ratio differs from the ratio 2.50 upon which the original computations of column areas were made, the difference will probably have little effect upon resulting wind stresses, these being influenced mainly by the relation between girder moments of inertia in the different bays. This relation is found as follows:

Floor	Moments of inertia, I, for: G_O	G_I
1	2,033.8	9,738.8
2	2,033.8	9,738.8
3	2,033.8	9,738.8
4	1,478.3	6,856.8
5	1,246.8	6,354.7
6	1,246.8	6,354.7
7	1,246.8	6,354.7
8	1,246.8	6,354.7
9	1,246.8	6,354.7
10	1,246.8	6,354.7
	15,060.5	74,201.4

$$\begin{array}{lcrcr} \text{Average } I & = & 1{,}506.05 & = & 7{,}420.14 \\ \text{Average } K & = & 75.30 & & 247.30 \\ \text{Ratio } \dfrac{G_I}{G_O} & = & \dfrac{7{,}420.14}{1{,}506.05} & = & 4.92 \end{array}$$

This value checks reasonably well with 4.70 which was previously determined and used in proportioning the inner girders.

ANALYSIS OF A "COMPROMISE 3-STORY BENT"

The computation of the compromise 3-story bent shown in Fig. 2 is as follows:

Determination of K-Percentages.—From the K-values at the joints:

75.30	99.90	75.30

Determination of Reaction Ratio R.—

$$\begin{array}{lcl} 0.181 & & 0.754 \\ 0.147 & & 0.605 \\ \underline{0.147} & & 0.605 \\ & & \underline{1.836} \\ 0.475 \times \dfrac{95.17}{24.60} & = & 3.800 \div 20 = 0.1900 = R_O = V_O \end{array}$$

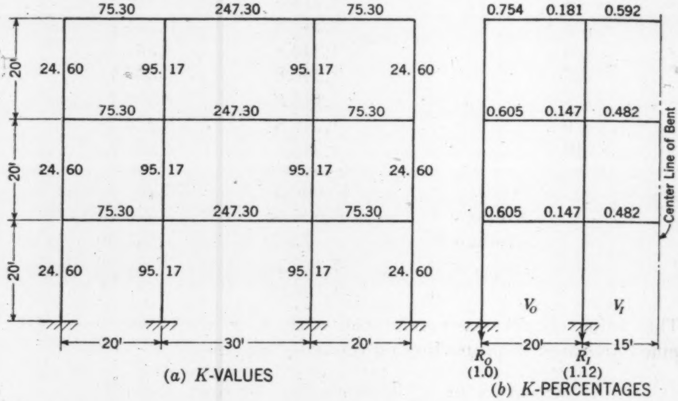
$$\begin{array}{l} 0.592 \\ 0.484 \\ \underline{0.484} \\ 1.560 \times 2 \times \dfrac{95.17}{24.60} = 12.120 \div 30 = 0.4040 = V_I \end{array}$$

$$V_I - V_O = 0.2140 = R_I$$

$R = \dfrac{R_I}{R_O} = 1.12$. Hence, if $R_O = 1.0$, $R_I = 1.12$.

This checks closely with 1.09 in original calculations. The design is therefore consistent with the cantilever reaction relation.

Should a discrepancy be found great enough to necessitate further computation, the wind reactions for the new reaction ratio R may be found readily as was done before, and the new wind moments in girders found by simple proportion from those in Fig. 1, the outer girder moments being obtained by multiplying the former moments by the ratio of the respective outer vertical wind shears V_O $(= R_O)$ and the inner girder moments by multiplying the former moments by the ratio of respective inner vertical wind shears V_I $(= R_O + R_I)$. Column moments result, as before, from the condition that $\Sigma M = 0$ at each joint, with special procedure in the first story.



(a) K-VALUES

(b) K-PERCENTAGES

FIG. 2.—COMPROMISE THREE-STORY BENT

The sizes of girders and columns may then be checked against these new moments, and changes made where required. Generally if the first design was made carefully to accord with the proper ratio of I's for inner and outer girders, found as described, such corrections will be very slight, even if required at all.

The proposed method of designing for cantilever behavior, and the K-percentage method for obtaining wind reaction ratio R for any design, may be applied to bents of any number and spacing of bays. The latter principle is particularly useful in the investigation of wind stresses in existing structures or in designs that have been made without due consideration of their elastic action.

As a final check on the accuracy of the foregoing wind-moment computation, a moment-distribution analysis[7] was made for the design. In Table 3, comparisons are made with the average of the Cross moments at the two ends of any member; in other words, the total moments in the member are compared. These show a very good agreement. All differences are of negligible proportions except in one bottom column (16%) and in certain members in the ninth and tenth floors and stories. The latter show differences as high as 26%; but as the actual moments are very small the sizes used are ample without change. Such a result may generally be relied upon. Ordinarily, large percentage discrepancies in wind moments near the top of the bent are of but little practical importance in the design of members.

TABLE 3.—CHECK COMPUTATIONS OF MOMENTS FOR COMPARISON

The design was made using moments at the center of intersections for all girders and columns. If it is desired to use moments at the face of columns or at the top or bottom of girders, corresponding corrections may always be made, in proportioning the members. The most practicable way to do the original computation is to consider moments at the centers of intersections of members.

If it is found that the horizontal deflection of the building exceeds a proper assigned proportion of its height, a correction may be applied readily by making a proportional reduction in the allowed column unit stress, keeping the stiffness relation unchanged between outer and inner columns. A change in girder stiffness will have little effect upon deflection. The deflection can be computed from column wind moments at either inner or outer column, in the manner described elsewhere.[10]

In general, a design based on the assumption of a cantilever relation between vertical wind reactions may not be the most economical as to weight although it is to be recommended because it eliminates secondary wind bending moments due to axial distortion of columns under direct wind stresses.

For 3-bay bents, the loss in economy will be greater when the width of the inner bay is relatively greater. This is apparent since in such cases the inner girders G_I are longer; and the foregoing computations show that, in order to produce the cantilever relation of wind reactions, the sections of these girders must be increased arbitrarily above the requirements for vertical loads alone.

---

[10] *Proceedings*, Am. Soc. C. E., February, 1932, p. 229.

GENERAL APPLICABILITY OF *K*-PERCENTAGE METHOD

It should be remembered that the *K*-percentage method is not limited to the type of case considered herein—namely, one in which vertical wind reactions are made to accord with the cantilever relation—but is applicable to any sizes that may exist in the bent, and to a bent of any number and any relative width of bays. It is particularly useful in the investigation of wind stresses in an existing bent, for which the assumptions as to wind distribution which were made in its design are unknown.

If it is not considered necessary to maintain the cantilever relation of vertical wind reactions, the bent may first be designed throughout for vertical loads alone. Using the sizes thus obtained, wind reaction ratios are found by the *K*-percentage method and from these ratios wind moments are computed. The members are then re-designed to include these wind moments and finally a *K*-percentage check is made on wind-reaction ratios. These operations are similar to those described in the foregoing example. If the reaction ratios last found do not vary too greatly from those used in computing the wind moments, no further change in sizes is required. In this connection it should be noted that a considerable variation may occur in the values of wind reaction ratios without materially changing the wind moments.[11] For this reason a second revision of design will generally be unnecessary.

---

DISCUSSION

C. M. Goodrich,[12] **M. Am. Soc. C. E.**—Mr. Witmer's paper is a corollary to the Witmer Method in the Sixth Progress Report of the Committee on Wind Bracing in Steel Buildings,[2] where it was shown that, for cantilever action, multiplying each bay shear by the bay width gives a result proportional to the *K*-value of the girder treated. It supersedes clumsier methods, and gives a welcome program of calculations for one to follow.

In summing loads on the columns, the axial wind load is apparently omitted. In the design of outer columns C_O, first story, one might consider this computation:

Vertical load	$= 300 @ 12 = 25$ sq in.
Axial wind load	$= 95$
Axial wind bending $78 \times 12 \times \frac{c}{r^2}$	$= \underline{200}$
Top of column	$595 @ 18 \times \frac{4}{3} = 24.8$ sq in.

It is conceivable that in buildings of great height, and of relatively small lower story height, the axial load from wind would be of more importance than the wind bending.

Under the heading "Proposed Method of Design: Second Story," the average *K*-ratio of the column is found to be 3.87; the columns tentatively selected have a *K*-ratio of 3.77. The value of 2.50 given in the text refers to the relative areas of the tentative columns.

A little difference in the sequence of calculations might be considered desirable. If alongside Fig. 1 one places the total moments to points of contraflexure, then the axial wind loads may be calculated from them by one setting of the slide rule for C_O, dividing by 102.7; C_1 loads may be found from these, also by one setting. Moments in G_O may then be found by multiplying successive differences by the half girder length, and moments in G_1 taken in ratio to these.

The moment in G_O and C_O in the tenth floor may be approximated, on the high side, by taking the shear in C_O as $10 \times \frac{1}{6.18} = 1.62$, and multiplying by the half height or half bay 10, giving 16,200 ft-lb. Unfortunately such a procedure gives results increasingly too great as one goes down the column.

Among the "exact" methods is that of Georg Unold,[13] including wind and vertical loads in one equation per joint. It is an end-tangent method, of course, after the Mohr-Greene, elastic-weight, area-moment, graphical integration devices, as used sometime in the last century by the late Prof. C. E. Greene, M. Am. Soc. C. E., in an undated pamphlet entitled "Partially Braced Frames," given to the writer by his son about 1903. A line in this pamphlet indicates that Professor Greene regarded area moments as graphical integration. Professor Mohr introduced angle changes as unknowns in 1892.

---

[12] Cons. Engr., The Canadian Bridge Co., Ltd., Walkerville, Ont., Canada.

[13] "Die Praktische Berechnung der Stahlskelettrahmen," by Georg Unold, W. Ernst und Sohn, Berlin, 1933.

Professor Unold suggests that in many cases the stiffness of the end walls may be such as to justify disregarding sway in interior bents, in view of floor stiffness. It is interesting to speculate as to whether it is better to make end walls adequate, or to make the interior bents adequate but capable of acting effectively only after the walls are shattered.

It would be of interest if Mr. Witmer would give an exposition of his favorite method of calculating sway in his closure.

Francis L. Castleman, Jr.,[14] **Assoc. M. Am. Soc. C. E.**—For the mathematically minded, or those who insist on extreme refinement in the accuracy of the assumptions and calculations, the *K*-percentage method of wind stress analysis will offer little appeal. To practicing engineers who, on occasion, must utilize the conventional methods, either theoretical or approximate, the *K*-percentage method and the accompanying new method of cantilever design offer a means whereby wind stresses can be determined with an accuracy approaching the so-called theoretical methods, and with little more time than that required for the simplest of the approximate methods. Verification of the accuracy of these new methods has been backed up by sufficient research, both analytical and experimental, to warrant full confidence in their use as presented.

The studies evolving these new methods, although very circumspect in the cases and conditions considered, lead, upon thoughtful consideration, to questions definitely not considered by them, but to which they are unavoidably joined and for which additional information is needed. The method of *K*-percentages can be used on any tier building, as can the new cantilever theory; but, as inferred in the paper under "Present Methods of Design," the conventional approximate methods are satisfactory for buildings of the usual proportions. Inspection of the building codes of various cities, however, leaves one in a quandary as to what a building of the usual proportions is.[15] Lacking any conclusive information, analytical or experimental, the following three cases are proposed arbitrarily:

$$\text{Case 1;}\quad \frac{\text{Height}}{\text{Least width}} \leqq 2\text{; wind stresses neglected.}$$

$$\text{Case 2;}\quad \frac{\text{Height}}{\text{Least width}} \leqq 5\text{; wind stresses to be considered.}$$

$$\text{Case 3;}\quad \frac{\text{Height}}{\text{Least width}} > 5\text{; tower buildings; wind stresses to be carefully determined.}$$

Of course, it is assumed in cases 1 to 3, inclusive, that the same intensity of wind pressure exists. Modifications should naturally be made for allowable increases in unit stresses (*a*) where wind is involved (an almost universal specification) and (*b*) where wind is omitted over protected heights.

---

[14] Prof. and Head, Dept. of Civ. Eng., Univ. of Connecticut, Storrs, Conn.

[15] *Carnegie Pocket Companion*, 24th Ed., p. 357.

Cases 1 and 3 offer no difficulty. In case 1, assuming the cases divided correctly, no consideration need be given; in case 3 wind stresses must be determined carefully either by one of the theoretical methods or by the method of K-percentages, preferably based on the new cantilever method. For extreme upper limits a combination of methods may be preferable before final sizes are determined.

Case 2 is the range in which most buildings that require wind stress analysis occur. Offhand, it would be assumed that all buildings in this class can be designed by any one of the approximate conventional methods (probably either the portal or cantilever method). The writer has often questioned this and felt that in the upper limits of this range, say from 4 to 5, more careful consideration should be given, but that the great accuracy (somewhat imaginary) furnished by the theoretical methods was not necessary. The method of K-percentages here offers a method that is precisely suitable and, in this range (or an equivalent one), will find its maximum use.

A series of studies, either analytical, experimental, or both, to determine ranges similar (but not necessarily identical) to those given by cases 1, 2, and 3, would be most helpful to the designer, who could then at once classify his building and the method to be used in its design for wind. It would seem that this series of studies should be made by methods similar to those that evolved the method of K-percentages and was a logical extension of the same.

The author states under "Analysis of a Compromise 3-Story Bent" that "* * * a design based on the assumption of a cantilever relation between vertical wind reactions may not be the most economical as to weight although it is to be recommended * * *." This would appear contradictory and at least only partly true. Obviously, if used, the cantilever method of design will fall under case 3 and then should be used when the secondary moments from column shortening cause the sizes of the members to be in excess of those obtained by the new cantilever method. Secondary moments from column shortening are not objectionable provided they are cared for and that the sum total weight involved is less than that required by cantilever theory. Again it is suggested that a series of supplementary theoretical studies should be made determining an approximate height-to-least-width ratio where this change takes place. Such studies might in themselves lead to shorter methods for determining the secondary moments set up in the beams from column shortening.

The bent as designed in the paper offers several interesting possibilities for variation in design, subject to possible verification by future analytical and experimental investigation. Two cases will be considered, both dealing with the girders of the first floor. (A similar procedure can be followed for girders of the other floors if desired.) All sizes are based on gross section following a similar procedure used in the paper. Inside girder G_1, as designed, is a 36-in., 160-lb H ($I = 9{,}738.8$) and was determined from the fact that its moment of inertia must be at least 4.70 times that of outside girder G_O. For vertical load alone a 27-in., 91-lb H ($I = 3{,}129.2$) is sufficient. Suppose cover plates are added to this at each end to provide enough strength to furnish a moment of inertia of at least 9,560 in.^{4} Calculation shows that a 27-in., 91-lb H gives poor size covers and that the base section is changed to a 30-in., 108-lb H with covers $16 \times \frac{11}{16} \times 6.75$ ft top and bottom at each end. The point of contraflexure for combined loading is taken as three eighths the span of 30 ft, and 1 ft is added to the theoretical length of each cover. For the end portions $I = 9{,}602$ in.^{4} and for the center portion $I = 4{,}461$ in.^{4} The end portion comprises 22.5% of the 30-ft span. It should be noted that this girder should be connected to the column for its moment-resisting capacity rather than the total end moment of 8,025 kip-in. For shear it should be connected for its moment-resisting capacity divided by one half the span. With the foregoing arrangement the ratio of the end moment of inertia of the inside span to that of the outside span is 4.72. A weight saving of 11.4% is obtained. For total economy this saving would have to be balanced against the increased cost of fabrication. Obviously, the *K*-values have been upset and only by future additional studies could such a procedure be justified theoretically. However, it should be noted that the author has used cutoff cover plates on the first-story columns. In all fairness it should be stated that such a procedure has much less influence on the design than that of using cutoff covers on the girders.

A more rational method than the foregoing, and one conducive to greater economy, is as follows: Replace the author's design of the outer first-floor girder G_O by an 18-in., 55-lb H ($I = 889.9$) with covers $10 \times \frac{3}{8} \times 3.75$ ft top and bottom at each end. This gives an *I*-value in the end portions of 1,531 in.^{4} and in the center portion of 889.9 in.^{4} The point of contraflexure for combined loading is taken at three eighths the span of 20 ft, and 1 ft is added to the theoretical length of each cover. Sufficient resisting moment is furnished at all points. The end portion comprises 18.75% of the total span of 20 ft. A weight saving of 12.7% is obtained.

From the foregoing design multiply the *I*-values in the end and center portions of outside girder G_O by 4.70, giving theoretical values of $I = 7{,}200$ in.^{4} and 4,190 in.^{4}, respectively, to be used in the design of the inside girder G_1. Again, for the same reason, a 30-in., 108-lb H ($I = 4{,}461.0$) is used for the base section. Covers 5 ft long, top and bottom, are used at each end with the point of contraflexure for combined loading taken at three eighths the span of 30 ft. One foot is added to the theoretical length of each cover. Sufficient resisting moment is furnished at all points with the added feature that, in the end portions, $I = 7{,}221$ in.^{4} and in the center portion $I = 4{,}461.0$ in.^{4} The ratio of these *I*-values, respectively, to those in the side span is, for the end portion, 4.71; and, for the center portion, 5.01. These do not vary greatly from the theoretical value of 4.70. A weight saving of 24% in the inside bay is effected by this arrangement. The end portion comprises 16.70% of the total span of 30 ft.

The latter case, in which girders in the inside and outside bays are both cover-plated and the ratio of the moment of inertia is held to the value of 4.70 as nearly as possible, is more effective than the case in which cover plates were used only in the inside bay. That this is true is seen by the much greater saving in weight. However, it must again be emphasized that such a saving can be justified only by the verification of more extended investigations both analytical and experimental.

Professor Witmer's studies in wind stress analysis have opened up a new approach to this interesting field. Based upon both analytical and experimental evidence that is incontrovertible, they offer to the profession two new approaches that considerably simplify a somewhat difficult problem. As stated in this discussion the investigations can be extended considerably further and the writer sincerely hopes means can be found whereby this will be done. An interesting possibility would be an adaptation or modification to the Vierendeel truss. A tier building is no more than a cantilever Vierendeel truss.

CLYDE T. MORRIS,[16] M. AM. SOC. C. E.—The design procedure outlined by Professor Witmer gives results closely in accord with the Spurr method of design.[3] The fundamental relationship on which the *K*-percentage method is based ("that I_g varies as $V_g L^2_g$"), so far as the writer is aware, was first called to the attention of the profession and utilized as a basis for design in a paper, read at the meeting of the Structural Division of the Society on October 13, 1927, entitled "The Design of Tall Building Frames to Resist Wind,"[17] by the writer in collaboration with A. Ward Ross, Jr. Instead of the *K*-percentage method as developed by Professor Witmer, the writer's paper presented a chart showing the variations in girder shears due to changing ratios of column-to-girder *K*'s.

In discussing Table 3 Professor Witmer states that when the horizontal deflection of the building exceeds a proper assigned proportion of its height, it may be corrected by making a proportional reduction in the allowed column unit stress, keeping the stiffness relation unchanged between outer and inner columns. According to Professor Witmer: "A change in girder stiffness will have little effect upon deflection." This is in direct contradiction to the statement made earlier, in his discussion of Table 2: "The effect upon the wind-reaction ratio of a change in the relative size of girders is much more pronounced than is the effect of a similar change in columns."

It is also at variance with the facts, as shown by the following computations.[18] Fig. 3 shows the elastic lines of the members at a floor with the deflections greatly exaggerated. The drift due to column bending is ϕh and that due to girder bending is θh. From area moments,

$$\phi = \frac{H_c h^2}{12 E I_c} \quad \text{(4a)}$$

and

$$\theta = \frac{V_g L^2_g}{12 E I_g} \quad \text{(4b)}$$

Using the stresses and member sizes given by the author for the first floor: For column C_O(12-in. 85-lb H), $\phi_O = \frac{10.47\ (2 \times 8 \times 12)^2}{12\, E\, 723.3} = \frac{44.4}{E}$; for column C_I (14-in. 237-lb H), $\phi_I = \frac{39.53\ (2 \times 8 \times 12)^2}{12\, E\, 3{,}080.9} = \frac{39.4}{E}$; for girder G_O

---

[16] Prof., Civ. Eng., Ohio State Univ., Columbus, Ohio.

[17] *Proceedings*, Am. Soc. C. E., May, 1928, p. 1395; see also *Bulletin No. 48*, Eng. Experiment Station, Ohio State Univ., Columbus, Ohio.

[18] *Bulletin No. 93*, Eng. Experiment Station, Ohio State Univ., Columbus, Ohio.

(24-in. 74-lb **WF**), $\theta_O = \dfrac{16.55\,(20 \times 12)^2}{12\,E\,2{,}033.8} = \dfrac{39.0}{E}$; and for girder G_I (36-in. 160-lb **WF**), $\theta_I = \dfrac{34.6\,(30 \times 12)^2}{12\,E\,9{,}738.8} = \dfrac{38.4}{E}$.

Thus, for the author's design, the effect of girder flexure on deflection is about equal to the effect of column flexure. If the story height were about 12 ft instead of 20 ft, as is usual in most buildings, the effect of column flexure would be still less.

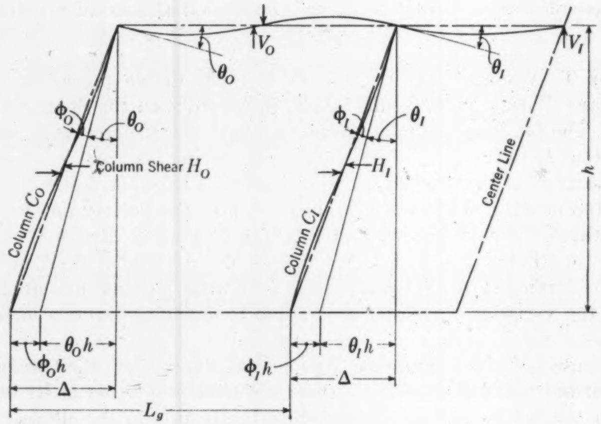

FIG. 3

When it is desirable to reduce the deflection of the bent, the girder stiffnesses should be increased. The column flexure has little effect upon the total deflection. The deflection due to direct lengthening and shortening of the columns (chord deflection) is still smaller.

OTTO GOTTSCHALK,[19] ESQ.—For more than a century structural analysis has been almost entirely characterized by abstract mathematical speculation. This is especially true of the eighties. It seems as if this trend was started by specialists to establish—as a mystery—the art of expressing simple relations in endless formulas and equations. Even today this characteristic of structural analysts is admired and emulated the world over. In the United States, writers of textbooks have mitigated the learned excesses, but fundamentally confusing and complicating expressions such as "redundants," "least work," etc., still abound—concepts that are not essential to the type of structure to be designed. The present trend is toward simplified methods of balancing moments or rotations, such as that developed by Professor Cross.[7] This symbolizes a much needed reaction to a study of how a structure acts in nature and of relative efficiencies. The cycles of computation, back and forth, to balance a disturbed equilibrium in a structure are easily perceptible to the analyst. Even these arithmetical devices are unnecessary, however, if the analyst will study, directly, the geometrical deformations that can be observed by the eye.

---

[19] Buenos Aires, Argentine Republic.

Professor Witmer states (see heading "Present Methods of Design") that "Of the so-called 'exact' methods, the 'slope deflection method' * * * and the method of end-moment distribution * * * are the most outstanding." This statement is incomplete. A form of visual experiment has been advocated by the writer for many years[20] as the logical basis of all structural analysis. A model composed of flexible splines, subjected to a unit geometrical alteration at any place, bends into curves which are the parts of the influence line for the stress represented by the flexed part. The resistance to rotation at the end of a member, of specific stiffness $K = \frac{I}{L}$, is the relative stiffness[21]

$$S = K\,(1 - 0.5\,m) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

This simple expression defines implicitly and automatically the end value of a balancing series and is obtained in a minimum of time.

One of the principal lessons derived from the use of splines is to keep the analysis of structures entirely separate from load and stress computations in order to avoid relapsing, even partly, into the former state of "learned" chaos. To analyze a structure for wind stress assume the upper floor (Fig. 4) to be pushed to the left by a unit distance 1. The columns then assume a curved form whose end tangents intersect the floor levels at distance *f* and *f'*, as shown at *B*. The resistance of any one column to the unit horizontal sway is:[22]

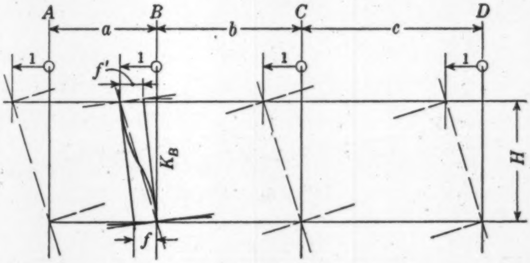

FIG. 4.—DISPLACEMENT "1" OF UPPER FLOOR

$$\Delta P = \frac{6\,E\,K\,(f' - f)}{H^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which, generally, *f* and *f'* have opposite signs and *P* is the force required to produce the unit displacement. Then $\frac{\Delta P}{\Sigma\,\Delta P}$ indicates the share absorbed by that column of the total horizontal thrust *P* acting at the upper floor. The per-

FIG. 5.—TYPICAL COLUMN SHEAR AND REACTIONS IN A SIX-BAY FRAME, FOR DIFFERENT COLUMN SPACINGS

centage thus obtained is multiplied by the horizontal thrust P to compute the thrust at each column. The thrust P does not enter and should not possibly be introduced into the geometrical analysis of $(f' - f)$ itself, yet that is what is being done all the time.

The ΔP values in every story are relative. Therefore, it is possible to introduce any simplification that affects all members in approximately equal proportions. Generally, in solving Eq. 6 for any single story $\frac{6\,E}{H^2}$ is canceled and (for example) it will be admissible to substitute S by $K = \frac{I}{L}$ for all the structural members, without affecting the results materially. Similarly, in structures generally the columns joining at the upper and at the lower floor of each story will influence the members of that story in equal proportions, and for the purpose of interior analysis, may be omitted.

Fig. 5 shows clearly[23] how the distribution of all these shears is influenced by the relative density of the columns at the sides, at the center, or at one side of the building, proving again that the load distribution is entirely different from that determined with the assumptions made in some of the older methods, as rightly emphasized by Professor Witmer.

Fig. 6 is the three-bay, 10-story bent presented elsewhere by Professor Witmer[24] which the writer has analyzed according to his views. It will be noted that the flexibility of exterior columns is exceptionally great in relation to the remainder of the structure. The analysis can be demonstrated as applied to the story between the sixth and fifth floors (Fig. 7).

Proportions: $\frac{0.932}{10.728} = 0.087$; $\frac{2.050}{10.728} = 0.191$; and $\frac{2.382}{10.728} = 0.222$.

$$\frac{M_a}{0.5\,M} = 0.087 + 0.191 = 0.278; \qquad S_a = -R_A = \frac{M_a}{10} = 22.24 \text{ kips}$$

$$\frac{M_b}{0.5\,M} = 0.222 + 0.222 = 0.444; \qquad S_b = \frac{M_b}{15} = 23.68$$

Reaction at column B: $R_B = S_b - S_a = +1.44$ kips

The shear at the columns between the fifth and sixth floors may be computed as follows:

$$2\,K_A\,\theta_a = \frac{2 \times 1.137 \times 5.195}{5.195 + 2 \times 1.137} = 1.583$$

$$K_B\,\theta'_a = \frac{3.388 \times 5.195}{5.195 + 3.388} = 2.050$$

$$K_B\,\theta_b = \frac{3.388 \times 8.010}{8.010 + 3.388} = 2.382$$

Sum each side of center line 6.015

Total, 2 × 6.015 each at bottom and top = 12.030

$$\text{Section modulus for this level: } \frac{I}{c} = \Sigma K(\theta - \theta') = 24.060$$

$$\text{Proportions: } \frac{1.583}{12.030} = 0.132; \qquad \frac{2.050}{12.030} = 0.170; \quad \text{and} \quad \frac{2.382}{12.030} = 0.198.$$

$$S_A = 90 \times 0.132 = 11.88\ K; \quad \text{and} \quad S_B = 90\ (0.170 + 0.198) = 33.12\ K.$$

Table 4 shows the bending moments obtained by the foregoing analysis in girders and columns respectively, compared with the average moments of the Cross method and the moments of the Witmer methods. It will be seen that the writer's results are close to the average of the Cross moments and generally between Professor Cross and Professor Witmer.

The lower part of Fig. 7 shows the column pressures and column shears produced by the 90 kips of wind pressure acting at the sixth floor, and by the $M = 1{,}600$ kip-ft of moment, quite distinct again from general, arbitrary assumptions.

Knowing the accumulated column pressures, and their shortening or lengthening in relation to the nearest column, the correction is simple enough to determine by Eq. 6, substituting for H the length L of the connecting beam between columns.[20] Additional important data obtained by the writer[20] are the section modulus and "accumulated sway" in Fig. 6, which facilitate a valuable comparison for the flexibility of different column arrangements in a bent.

Altogether the merits of Professor Witmer's paper and the *K*-percentage method cannot be questioned, especially in comparison with the results of the older arbitrary methods; but a method, not contained in the structure itself, is not needed if it is analyzed in the manner suggested herein. The three-bay, 10-story bent is most convenient for training purposes and demonstration; yet results obtained with it do not apply to the irregular bents encountered in daily practice, where exterior columns are less flexible compared with the other members of the structure.

F. P. Witmer,[25] M. Am. Soc. C. E.—It is gratifying that Professor Morris believes that the design procedure outlined in the paper gives results closely in accord with the Spurr method of design. This was a main incentive in preparing the paper.

Professor Morris states that the writer has made contradictory statements regarding the effect upon deflection of a change in girder stiffness. This criticism is not quite warranted. The statement made by the writer in discussing Table 2 was with reference to the effect of such change upon the wind-reaction ratio, and not upon deflection. The effect upon the reaction ratio was amply demonstrated[26] in the model study by the writer and H. H. Bonner published in 1936. The effect upon deflection is less obvious. The writer has made a further study, results of which do not support his original views regarding deflection as expressed in his present paper. This study will be commented upon later.

Professor Morris' Eqs. 4*a* and 4*b* are not properly applicable unless the point of contraflexure lies on the straight-line axis of the member, which can occur only when this point is at midlength. Therefore, it is quite incorrect to apply Eq. 4*a* to the first-story column. To do so results in an error of nearly 150% in the value of ϕ_O.

The discussion of Professor Morris was very stimulating and impelled the writer to make a further effort to satisfy himself as to the facts in the matter. The writer stated that a change in column stiffness would have a greater effect upon deflection than a change in girder stiffness. Professor Morris states that

---

[25] Director, Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.

[26] "Tall Building Frames Studied by Means of Mechanical Models," by F. P. Witmer and H. H. Bonner, *Transactions*, Am Soc. C. E., Vol. 102 (1937), p. 416.

"When it is desirable to reduce the deflection of the bent, the girder stiffnesses should be increased. The column flexure has little effect upon the total deflection." The writer's investigation leads him to conclude that neither of these statements is correct, but that an increase in either girder size or column size alone will have only a negligible effect upon deflection, and that, to produce an appreciable reduction in deflection, both girders and columns must be increased in approximately equal proportions. In other words, the stiffness of the bent as a whole must be increased. If the bent is made twice as stiff, the deflection will, of course, be reduced by one half.

[a] $V_O = R_O = \frac{983.9 + 949.2}{20}$ = 96.65, etc. [b] $R = \frac{R_I}{R_O}$ = 1.080, etc. [c] $V_I = \frac{\Sigma M \times 2}{30}$ = 201.07, etc.
[d] $R_I = V_I - V_O$ = 104.42, etc.

Two new designs were compared with the design in the paper. In the first of these the girders were doubled in stiffness, and in the second the columns were doubled, other parts remaining as in the original design. Both designs were checked by the Cross method. The wind-reaction ratios were found to be practically the same in all three cases, as was to be expected, since the relation between inner and outer columns and between inner and outer girders was unchanged, the assumed cantilever relation of reactions thus being maintained. The surprising fact was noted, however, that the wind moments in girders and columns throughout the bent were also practically the same in all three cases.

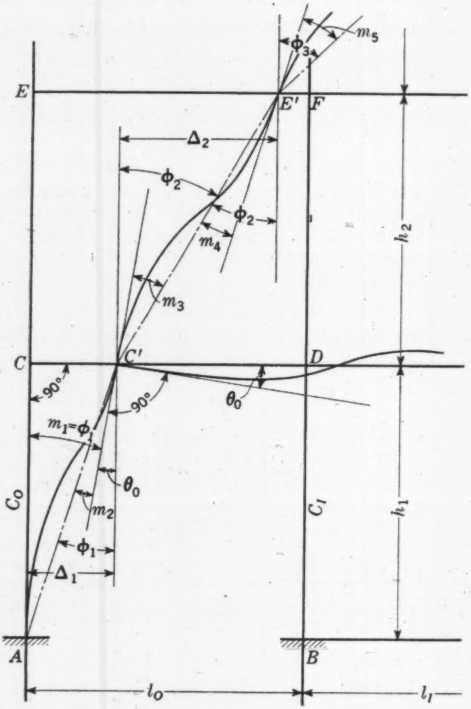

FIG. 8

Table 5 shows the moments computed for the three bents. This result should not be surprising, since it would necessarily follow from the similar wind-reaction ratios if the *K*-percentage method of analysis were used, and in every one of the many cases previously tested by the writer[2] the moments found by this method were seen to be very closely in accord with those obtained by the Cross analysis.

Deflections were next computed for all three cases. Instead of following the method suggested in the Second Progress Report of the Sub-Committee on Wind Bracing,[27] the writer used a much simpler method. End-deflection angles m_1, m_2, m_3, etc., for columns shown in Fig. 8, were computed from the column moments by the method of slope deflection. The formula for this is

---

[27] *Proceedings*, Am. Soc. C. E., February, 1932, p. 213.

$$m_1 = \frac{M_2 - 2\,M_1}{6\,E\,K} \qquad (7)$$

From these angles, the angles ϕ_1, etc., being the slopes of the straight-line axes of the columns with reference to the vertical, were found as follows:

$$\left.\begin{aligned} \phi_1 &= m_1 \\ \phi_2 &= \phi_1 - m_2 + m_3 \\ \phi_3 &= \phi_2 - m_4 + m_5, \text{ etc.} \end{aligned}\right\} \qquad (8)$$

It is seen that the terms $(\phi_1 - m_2)$, $(\phi_2 - m_4)$, etc., in Eq. 8 represent angles identical with θ_O, etc., in the discussion of Professor Morris, and therefore correspond to what he terms the "girder drift," whereas m_3, m_5, etc., are comparable to Professor Morris' ϕ_O, etc., and represent "column drift."

From these values of ϕ_1, ϕ_2, etc., the deflections in the several stories will equal, respectively, $\phi_1\,h_1$, $\phi_2\,h_2$, etc.; and since, in the case under consideration, the story height is the same for all floors, the total deflection will be

$$\Delta = (\phi_1 + \phi_2 + \phi_3, \text{ etc.}) \times h \qquad (9)$$

This procedure produced the results that follow:

Case I, Witmer Design—$\Delta = 5.592$ in. (by outer column moments); column drift = 65.7%; and girder drift = 34.3%. (By inner column moments, $\Delta = 5.760$ in.—a good check.)

Case II, Girders Doubled—$\Delta = 4.932$ in. (a reduction of 11.6%); column drift = 74.2%; and girder drift = 25.8%.

Case III, Columns Doubled—$\Delta = 5.136$ in. (a reduction of 8.2%); column drift = 32.0%; and girder drift = 68.0%.

Thus, an increase of 100% in either girders or columns reduced the deflection by only about 10%, which was not enough to be of great practical value, when compared with the increased weight of metal involved. The relative effect upon column and girder drift in each case, however, was of the nature to be expected from the character of change made in sizes.

It thus seems reasonable to conclude that a reduction in deflection of an effective proportion would require an increase in both columns and girders. This result was so surprising and so conclusively established for the particular cases considered that the writer felt justified in presenting it rather fully, particularly as it seems so at variance with the expressed views of Professor Morris.

The discussions of Mr. Goodrich and Professor Castleman are both interesting and gratifying. The foregoing method of computing deflection may be considered by Mr. Goodrich as a response to his query in this regard The omission of direct wind stress in the design of columns, which was mentioned by Mr. Goodrich, was an oversight, pure and simple, and fully deserves his criticism; but it does not seriously affect whatever utility the paper may have in regard to its announced purposes.

Referring to Professor Castleman's discussion, the reason for the suggestion that it is better to use the cantilever relation of reactions in design, even though maximum economy may not result, is not because of any objection to secondary stresses from direct column wind distortion, "provided they are cared for and that the sum total weight involved is less than that required by cantilever theory." The real reason is that without the cantilever relation these stresses must be computed, and their determination is quite laborious, requiring an additional moment-distribution analysis based upon the direct column wind distortions. It was considered that the comparatively small loss in economy to be expected might be properly offset against this increased cost of analysis, although the writer realizes that an increased cost in engineering processes is not generally a valid reason for entailing an additional cost of steel. The matter is largely one of judgment on the part of the designer.

The writer has not had time to study further the effect of a variable moment of inertia in girders upon the availability of the *K*-percentage method, but he believes that the principles underlying this method are so fundamentally applicable that it can be adapted readily to such a modification in detail.

Mr. Gottschalk's discussion very acceptably presents the methods of bending behavior that he has described on many occasions, and had the writer possessed greater familiarity with these methods he would surely have mentioned them in conjunction with those of slope deflection and end-moment distribution, as a practical type of design procedure.

It is interesting to note the close comparison of the moments as computed by Mr. Gottschalk's method with those as computed by the Cross and the *K*-percentage methods, in the case considered by Mr. Gottschalk.

SIMPLIFIED THEORY OF THE SELF-ANCHORED SUSPENSION BRIDGE

By C. H. Gronquist,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. J. Meehan, C. B. McCullough, Jaroslav J. Polivka, William Bertwell, A. A. Eremin, and C. H. Gronquist.

Synopsis

The theory of the self-anchored suspension bridge is presented in this paper in a simplified form that lends itself to a straight-forward and expeditious analysis of that type of structure.

The self-anchored suspension bridge, unlike the externally-anchored type, may be properly analyzed by the elastic theory, since the effect of distortions under live load is practically eliminated in this "closed" structure. The formulas which follow are therefore based on the elastic theory.

Vertical camber of the stiffening girder is effective in reducing cable and girder stress in the self-anchored bridge by the arch-like action of the cambered girder, and this factor is included throughout. Moreover, as the resultant stress in the girder, like that in an arch rib, is that produced by direct thrust and moment, influence lines for girder flange stress may be constructed as for moment about the kern points of the girder. This method of stress analysis is used in the computations, which illustrate the application of the theory of the self-anchored suspension bridge.

The formulas for the self-anchored suspension bridge have been derived for a three-span symmetrical bridge with continuous girders. By dropping the continuity terms, the formulas for girders hinged at the towers are obtained. It will be observed that these formulas, with girder camber and shortening eliminated, are the same as those for the externally-anchored suspension bridge analyzed by the elastic theory.

Constant girder moment of inertia within each span has been assumed; the effect of this approximation, as well as that of neglect of suspender elongation, is considered, as is the modification of the formulas for unsymmetrical and multiple spans. A method of correcting the value of cable and girder H as

Note.—Published in February, 1941, *Proceedings*.

[1] Assoc. Engr., Robinson & Steinman, New York, N. Y.

computed by the elastic theory, in order to take into account the movement of the ends of the girder produced by its vertical deflection, is indicated.

INTRODUCTION

In the self-anchored suspension bridge the cable is attached to the stiffening girder at the outer ends of the side spans. Thus the horizontal pull of the cable is resisted by the girder in compression, and the anchorage foundations are subjected only to the upward vertical component of the cable stress, in addition to the girder reactions. This type of construction, consequently, permits the use of a suspension structure where foundation conditions do not justify the ordinary externally-anchored suspension bridge, with anchorages that must resist the horizontal pull of the cable.

There is some doubt as to whether the self-anchored suspension bridge was originated by an Austrian, Joseph Langer, in 1870, or whether that type of structure was covered by an American patent issued to Charles Bender in 1867. Although Bender's design and Langer's Wrsowic Bridge (1870) were of the self-anchored type, the cable was attached to the girder in the main span as well as at the outer end of the side spans of these bridges. The first truly self-anchored suspension bridge of the modern type was built at Lübeck, Germany, in 1899. The self-anchored suspension bridge has since been adopted extensively in Europe and in one instance in Japan. In the United States three almost identical examples of this type of bridge were built from 1926 to 1928 in Pittsburgh, Pa. Two bridges have also been built in the United States in which rolled beam girders and open-strand cables were used—the first in 1933 over the Little Niangua River in Missouri, and the second in 1939 with a 350-ft main span over the Wabash River in Indiana. In Guatemala a small self-anchored bridge was built in 1937 on the Pan-American Highway. (Howard Mullins, in 1936, supplied a list and bibliography of the self-anchored suspension bridges of the world.)[2]

Although several of these bridges are of moderately long span, ranging from 600 ft to 1,000 ft, most of them are approximately 400 ft, or less, in length of main span. The application of this type of structure to spans of less than 400 ft—in which, for light loading, rolled beams can be used as stiffening girders and open-strand construction for the cables, and where the shortness of span will lessen the disadvantage that deflection does not appreciably relieve girder moment—appears to offer distinct possibilities for improving appearance in bridges of this size in locations which would not be considered suitable for the externally-anchored suspension bridge.

So far as is known to the writer, no complete treatise on the theory of the self-anchored suspension bridge is available in English, although some valuable information has been published on the subject. (Computations for several self-anchored suspension bridge designs were presented by G. G. Krivoshein in 1930;[3] and, as stated, a review of the history and analysis of the characteristics of this type of structure was published by Mr. Mullins in 1936.[2]) The following is offered as a simplified statement and extension of the existing treatments of the theory of the self-anchored suspension bridge in the belief that, with a more complete, simplified treatment available, the use of the self-anchored suspension bridge for spans of moderate length will increase.

NOTATION

The letter symbols in Fig. 1 and elsewhere in the paper are defined in the text where they first appear and, for convenience of reference, are listed alphabetically in the Appendix.

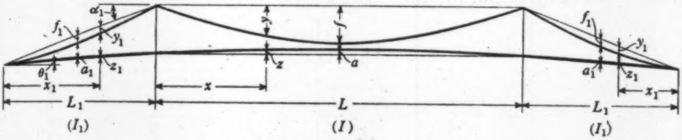

FIG. 1.—NOTATION DIAGRAM

DEAD LOAD

The stiffening girder, of symmetrical cross section and constant depth, of a self-anchored suspension bridge is subjected to no dead-load moment provided it is laid out during fabrication for dead-load position, and that the lengths of the towers, cable, suspenders, and girder are fabricated correctly to bring the girder exactly to this position after the application of the dead load. If the girder is cambered parabolically in any span, it will carry a portion of the uniformly distributed dead load as a parabolic arch, the total stress being axial. If the side-span cable is unloaded, the side-span girder must naturally be self-supporting for dead load, and when, in addition, the girder is continuous through the towers, it will be subjected also to dead-load bending stress in the main span. The latter type of structure is not considered herein; but by including this dead-load moment in the formulas that follow, they become applicable to that type of structure.

To determine the value of the horizontal component of cable and girder stress due to dead load, the expression for moment in the girder at the center of the main span may be written and placed equal to zero. In Fig. 2 let:

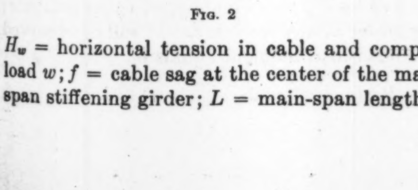

FIG. 2

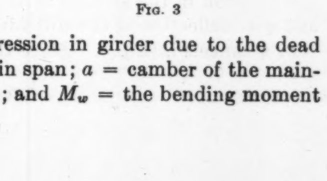

FIG. 3

H_w = horizontal tension in cable and compression in girder due to the dead load w; f = cable sag at the center of the main span; a = camber of the main-span stiffening girder; L = main-span length; and M_w = the bending moment due to dead load. Then,

$$M_w = \frac{w\,L^2}{8} - H_w\,a - H_w\,f = 0 \qquad (1a)$$

and

$$H_w = \frac{w\,L^2}{8\,(f + a)} \qquad (1b)$$

The portion of the dead load carried by the girder as a parabolic arch (w_a) may be evaluated by taking the second derivative of the expression for the negative moment that tends to act on the girder as a result of its parabolic camber. The expression for this moment is:

$$M_w' = -\,H_w\,z = \frac{-4\,a}{L^2}(L\,x - x^2)\,H_w \qquad (2a)$$

and

$$w_a = \frac{d^2}{dx^2}(-\,H_w\,z) = 8\,H_w\,\frac{a}{L^2} = \frac{w\,a}{f + a} \qquad (2b)$$

in which: z = main-span stiffening girder ordinate; and x = abscissas along the center span, measured from the tower. The value of the side-span cable sag f_1 is obtained by writing, as in the main span, the expression for moment in the girder at the center of the span (see Fig. 3):

$$M_{w1} = \frac{w_1\,L_1^2}{8} - H_w\,(f_1 + a_1) = 0 \qquad (3)$$

and therefore,

$$f_1 = \frac{w_1\,L_1^2}{w\,L^2}(f + a) - a_1 \qquad (4a)$$

Again (see Eq. 2*b*):

$$w_{a1} = \frac{w_1\,a_1}{f_1 + a_1} \qquad (4b)$$

LIVE LOAD

The application of live load to the bridge produces deflections of the cables and stiffening girders that change the dimensions of the structure. The changes in cable span lengths due to tower-top movement are negligible since they are small in proportion to the total span lengths. That the proportionately large changes in cable sag and girder camber have no effect on the moments in the girder may be seen by writing the general expression for moment in the girders (see Fig. 4):

$$M = T + M_D + M_0 - (H_w + H)\,(y + \eta) - (H_w + H)\,(z - \eta) \qquad (5)$$

in which: M = the total resultant bending moment at any section x of the stiffening girder; T = bending moment at any section x due to continuity; M_D = simple-beam bending moment for dead load; M_0 = simple-beam bending moment due to a live load p; H = horizontal tension in the cable and compression in the girder due to a live load p; y = main-span cable ordinate; and η = deflection of the stiffening girder at any section x. It will be observed that η cancels in Eq. 5. Since the dead-load moment equals 0,

$$M_D - H_w\,(y + z) = 0 \qquad (6a)$$

and, in any span,

$$M = T + M_0 - H\,(y + z) \qquad \text{(6b)}$$

The load taken by the girder in moment is equal to the negative of the second derivative of that moment.

$$p_0 = \frac{-d^2 M}{dx^2} = p - \frac{8\,(f + a)\,H}{L^2} \qquad \text{(7)}$$

This is the difference between the applied distributed load p and that taken by the cable and by the girder as an "arch."

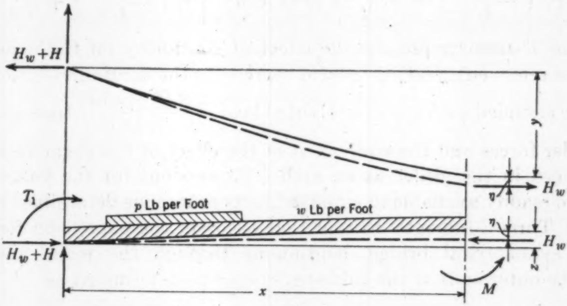

FIG. 4

Thus it may be stated that the self-anchored suspension bridge is an independent, closed structure, in its action under live load, in many ways more nearly resembling an inversion of the tied arch than an externally-anchored suspension bridge. Whereas the stresses in the latter type of structure are greatly affected by the changes in the cable sag produced by deflection, those of the self-anchored bridge are not so affected due to the simultaneous change in girder moment of H multiplied by the deflected z. Because the sum of $(y + z)$ or $(f + a)$ in any span is constant during deflection, neglecting suspender elongation, the value of the dead load H_w remains unchanged during deflection; the dead load carried by the girder-arch is decreased, that by the cable is increased.

Inasmuch, then, as the deflection of the bridge has no appreciable influence over the dead load H_w or the live-load moment in the girders, except over the latter in the side span when the side-span cable is unloaded, the self-anchored suspension bridge may be analyzed by application of the elastic theory. The following assumptions have been made:

(1) The cable curve before deflection is a parabola whose equation, with the closing chord as the x-axis and the origin at one end, is

$$y = \frac{4\,f\,x}{L^2}\,(L - x) \qquad \text{(8)}$$

in all spans.

(2) The girder camber is parabolic. (For a girder that lies in a straight line the a of the formulas (Eqs. 1 to 7) is made equal to 0.) With the closing

chord as the x-axis and the origin at one end:

$$z = \frac{4\,a\,x}{L^2}\,(L - x) \ldots\ldots (9)$$

in all spans.

(3) The average moment of inertia of the stiffening girder throughout each span is used as the constant I of that span.

(4) The work of deflecting the tower top is negligible.

The moment of continuity at any point may be written:

$$T = T_1'\left(\frac{L - x}{L}\right) + T_2'\,\frac{x}{L} + H\,(f + a)_m \left[e_1\left(\frac{L - x}{L}\right) + e_2\,\frac{x}{L}\right] \ldots (10)$$

in which the T'-terms represent the effect of continuity on the independent girder (cable removed), and the e-term represents the continuity effect on the girder of the assumed uniformly distributed load of $\frac{8\,(f + a)\,H}{L^2}$ from the sum of the suspender forces and the equivalent of the effect of the negative moment, $-H\,z$, induced in the girder as an arch. Expressions for the values of the T'-terms are readily available in standard texts or may be determined from the Theorem of Three Moments. From that theorem the expression for e for a three-span symmetrical bridge, continuous through the main towers but hinged at the outer ends of the side spans, may be determined as

$$e = e_1 = e_2 = \frac{2\,(1 + i\,r\,v')}{3 + 2\,i\,r} \ldots\ldots (11)$$

at the main towers and throughout the main span; in the side span the e-term varies from 0 at the free end to $e_{1,2}$ at the tower. In Eq. 11 (see Appendix): i = the ratio of moments of inertia, $\frac{I}{I_1}$, main span to side span; r = ratio of span lengths $\frac{L_1}{L}$, side span to main span; and v' = ratio of total sag and camber $\frac{f_1 + a_1}{f + a}$, side span to main span.

The general moment equation applying to all spans may be written in the following form as a working equation:

$$M = (T' + M_0) + H\,[e'\,(f + a)_m - (y + z)] \ldots\ldots (12)$$

In this equation e is written with a prime to indicate that it varies as a straight-line function within any span, and $(f + a)$ is written with the subscript m to indicate that it takes the main-span value in all spans; T', similarly to e, varies as a straight-line function within any span.

The vertical shear in the girder corresponding to this moment is in general form for all spans:

$$V = \frac{dM}{dx} = \left[\frac{(T_2' - T_1')}{L} + V_0\right]$$
$$- H\left[4\left(\frac{f + a}{L^2}\right)(L - 2\,x) - (f + a)_m\,\frac{(e_2 - e_1)}{L}\right] \ldots\ldots (13)$$

in which V_0 = simple-beam shear due to live load.

DETERMINATION OF H FOR LIVE LOAD

To derive the expression for H by the method of the redundant member, the cable may be conceived as cut, with the horizontal component of cable stress H the redundant. Then:

$$H = -\frac{\sum \frac{S'\,u\,L}{A\,E} + \sum \int_0^L M'\,m\,\frac{dx}{E\,I}}{\sum \frac{u^2\,L}{A\,E} + \sum \int_0^L m^2\,\frac{dx}{E\,I}} = \frac{N}{D} \quad\cdots\cdots\cdots\cdots (14)$$

In Eq. 14 S', the direct stress in the various members of the system with the cable cut, equals zero throughout; M', the moment in the members of the system with the cable cut, is the moment in the independent girder in each span; $M' = T' + M_0$ in all spans. The term u denotes the direct stress in the members of the system corresponding to a horizontal component of stress in the cable and girder of unity. In the cable $u = \frac{ds}{dx}$; and in the girders $u = \frac{ds'}{dx}$. The bending moment in the members of the system due to a unit horizontal component of cable stress is m. Calling $T' + M_0 = 0$ and $H = 1$ in the working equation for moment in the girders,

$$m = e'\,(f + a)_m - (y + z) \quad\cdots\cdots\cdots\cdots (15)$$

in all spans. The first term in the denominator of the H-equation (Eq. 14) is:

$$\sum \frac{u^2\,L}{A\,E} = \sum \int_0^L \left(\frac{ds}{dx}\right)^2 \frac{ds}{E_c\,A_c} + \sum \int_0^L \left(\frac{ds'}{dx}\right)^2 \frac{ds'}{E\,A_g} = \frac{L_s}{E_c\,A_c} + \frac{L_s'}{E\,A_g} \quad\cdots\cdots\cdots\cdots (16)$$

neglecting the effect of change of length of suspenders and tower legs. With a parabolic cable of constant section:

$$L_s = \sum L\,(\sec^3 \alpha + 8\,n^2 \sec \alpha) \text{ (very nearly)} \quad\cdots\cdots\cdots\cdots (17a)$$

For an eyebar cable in which A_c may be assumed to vary with the cable secant:

$$L_s = \sum L \left(\sec^2 \alpha + \frac{16\,n^2}{3}\right) \text{ (very nearly)} \quad\cdots\cdots\cdots\cdots (17b)$$

The values of A_c at the low point of each span are used with the value of L_s given in Eq. 17b.[4] In the same manner:

$$L_s' = \sum L\,(\sec^3 \theta + 8\,c^2 \sec \theta) = \sum L \text{ (very nearly)} \quad\cdots\cdots\cdots\cdots (17c)$$

The second term in the denominator of the H-equation (Eq. 14) is:

$$\sum \int_0^L m^2 \frac{dx}{E\,I} = \sum \int_0^L [e'\,(f + a)_m - (y + z)]^2 \frac{dx}{E\,I}.$$

---

[4] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), Eqs. 21*c* and 21*d*, p. 1145.

Thus for a three-span symmetrical bridge,

$$D = \left(\frac{L_s}{E_c\, A_c} + \frac{L_s'}{E\, A_g} \right) + \frac{(f + a)^2\, L}{3\, E\, I} \left(3\, e^2 - 4\, e + \frac{8}{5} \right)$$
$$+ \frac{2\, L_1}{3\, E\, I_1} [e^2\, (f + a)^2 - 2\, e\, (f + a)\, (f_1 + a_1) + \frac{8}{5} (f_1 + a_1)^2] \ldots \text{(18}a\text{)}$$

Abbreviating further, Eq. 18*a* may be written also as:

$$D = \frac{(f + a)^2\, L}{3\, E\, I} \left\{ \left(\frac{8}{5} + 3\, e^2 - 4\, e \right) + 2\, i\, r \left[\frac{8\, (v')^2}{5} + e^2 - 2\, e\, v' \right] \right.$$
$$\left. + \frac{3\, I}{(f + a)^2\, L} \left(\frac{E}{E_c} \times \frac{L_s}{A_c} + \frac{L_s'}{A_g} \right) \right\} \ldots\ldots\ldots\ldots \text{(18}b\text{)}$$

The numerator of Eq. 14 is: $- \sum \int_0^L M'\, m\, \frac{dx}{E\, I} = - \sum \int_0^L (T' + M_0)$ $\times [e'\, (f + a)_m - (y + z)] \frac{dx}{E\, I}$; but $\sum \int_0^L T' \left[e'\, (f + a)_m - (y + z) \right] \frac{dx}{E\, I} = 0$, which can be verified by integration. Therefore

$$N = - \sum \int_0^L M_0\, [e'\, (f + a)_m - (y + z)] \frac{dx}{E\, I} \ldots\ldots\ldots \text{(19)}$$

From the foregoing general expression for *N* (Eq. 19), the value of the numerator *N* of the *H*-equation (Eq. 14) for a specific bridge and various loadings may be derived by performing the indicated integration. A three-span symmetrical structure has been assumed in the cases that follow. For a concentrated load *P*, at a distance *k L* from the left tower in the main span:

$$N = - P\, (f + a) \frac{k\, L^2}{E\, I} \left[\frac{e}{2} (1 - k) - \frac{1}{3} (1 - 2\, k^2 + k^3) \right] \ldots\ldots \text{(20}a\text{)}$$

and

$$H = \frac{1}{D'\, n'} \left[B(k) - \frac{3}{2} e\, (k - k^2) \right] P \ldots\ldots\ldots\ldots \text{(20}b\text{)}$$

in which

$$D' = \frac{3\, E\, I\, D}{(f + a)^2\, L} \ldots\ldots\ldots\ldots \text{(21}a\text{)}$$

and

$$B(k) = k\, (1 - 2\, k^2 + k^3) \ldots\ldots\ldots\ldots \text{(21}b\text{)}$$

For a concentrated load at a distance $k_1\, L_1$ from the free end of the side span:

$$N = - \frac{P\, k_1\, L_1^2}{6\, E\, I_1} [e\, (f + a)\, (1 - k_1^2) - 2\, (f_1 + a_1)\, (1 - 2\, k_1^2 + k_1^3)] \ldots \text{(22}a\text{)}$$

and

$$H = \frac{i\, r^2}{D'\, n'} \left[v'\, B(k_1) - \frac{e}{2} (k_1 - k_1^3) \right] P_1 \ldots\ldots\ldots\ldots \text{(22}b\text{)}$$

in which

$$B(k_1) = k_1\, (1 - 2\, k_1^2 + k_1^3) \ldots\ldots\ldots\ldots \text{(23)}$$

By a process of integration over proper limits the values of N and H can be obtained from these expressions, for various distributed load conditions. For all spans fully covered with distributed loads of p in the main span and p_1 in the side spans:

$$N = \frac{-p\,L^3}{3\,E\,I}(f + a)\left(\frac{e}{4} - \frac{1}{5}\right) - \frac{p_1\,L_1^3}{3\,E\,I_1}\left[\frac{e}{4}(f + a) - \frac{2}{5}(f_1 + a_1)\right] \ldots (24a)$$

and

$$H = \frac{p\,L}{D'\,n'}\left(\frac{1}{5} - \frac{e}{4}\right) + \frac{2\,i\,r^3}{D'\,n'}\left(\frac{v'}{5} - \frac{e}{8}\right)p_1\,L \ldots\ldots\ldots (24b)$$

The value of N for the left or right half of the main span covered with a uniformly distributed load is one half the value for the entire span so loaded. Combined with the value of N for a side span fully loaded, this value is useful in obtaining preliminary values of the maximum moment at the tower and quarter-point of the main span. The value of N for the center 0.4 of the main span covered with a uniformly distributed load, which may be used in obtaining a preliminary value of the maximum moment at the center, is:

$$N = \frac{-p\,L^3}{E\,I}(f + a)\,(0.0473\,e - 0.0390) \ldots\ldots\ldots\ldots (25a)$$

and

$$H = \frac{3\,p\,L}{D'\,n'}(0.0390 - 0.0473\,e) \ldots\ldots\ldots\ldots\ldots\ldots (25b)$$

The several formulas given herein, for use in the computation of the live load H of a self-anchored suspension bridge, will all reduce, upon the substitution of f for $(f + a)$, y for $(y + z)$, and $L_s' = 0$, to those of the externally-anchored suspension bridge as derived by others[5,6] for the elastic theory.

TEMPERATURE

As the self-anchored suspension bridge is a "closed" structure, no temperature stresses are produced for conditions of uniform temperature change except those caused by the expansion of towers of unequal length below the girders. For the usual case in which the length of the main tower from pier to girder is greater than that at the free end of the side span, the stress produced, however, is merely that in the independent continuous girder as a result of the relative vertical movement of the main tower supports. The moment over the upward deflected supports for a symmetrical three-span girder is:

$$T_1' = T_2' = -\frac{6\,E\,\Delta y_t}{L_1\left(\frac{3\,L}{I} + \frac{2\,L_1}{I_1}\right)} = -\frac{6\,E\,I\,r\,\Delta y_t}{(3 + 2\,i\,r)\,L_1^2} \ldots\ldots (26)$$

The corresponding value of H is zero, neglecting the slight effect of horizontal movement of the ends of the girder and the rise of the tower saddles.

---

[5] "A Practical Treatise on Suspension Bridges, Their Design, Construction and Erection," by D. B. Steinman, M. Am. Soc. C. E., 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1929.

[6] "Modern Framed Structures," by the late J. B. Johnson and C. W. Bryan, Members, Am. Soc. C. E., and F. E. Turneaure, Hon. M. Am. Soc. C. E., 9th Ed., Pt. 2, John Wiley & Sons, Inc., New York, N. Y., 1911.

In the girder hinged at the towers there is no stress produced by the expansion of the towers, since the structure is fully articulated and free to deflect under uniform temperature change without causing stress. Towers fixed at their bases, however, are subject to temperature moments produced by the deflection of the tower tops with the cables.

LIVE-LOAD DEFLECTIONS

The equation of the girder deflection curve may be obtained by performing the double integration of the equation: $\frac{d^2\eta}{dx^2} = -\frac{M}{E\,I}$; from which—

$$\eta = -\int\int\left\{(T' + M_0) + H\left[e'\,(f + a)_m \frac{-4}{L^2}(f + a)\,(L\,x - x^2)\right]\right\}\frac{dx}{E\,I} \quad \text{..(27)}$$

The deflection of the girder at a particular point may be written from this general equation by the substitution of the proper coordinate, or by integration of the familiar equation:

$$\eta' = \int_0^L \frac{M\,m\,dx}{E\,I} \quad \text{.......................(28)}$$

The change of grade or slope of the deflected girder and roadway is found by integrating Eq. 27 once:

$$\tan\Delta\phi' = \frac{d\eta}{dx} = -\int\frac{M\,dx}{E\,I} \quad \text{..................(29)}$$

This slope of the elastic curve of the girder at a particular point is again found by the substitution of the proper coordinate in the general expression. At the towers—$x = 0$, or $x = L$. The formulas that follow have been derived for the three-span symmetrical bridge.

In the main span for a uniformly distributed load extending a distance $k\,L$ from the left tower, the equation of the deflection curve from $x = 0$ to $x = k\,L$ is:

$$\begin{aligned} E\,I\,\eta = &-\left[\frac{T_1'}{2\,L}\left(L\,x^2 - \frac{x^3}{3} - \frac{2\,L^2\,x}{3}\right) + \frac{T_2'}{6\,L}(x^3 - L^2\,x)\right] \\ &+ H\left[\frac{e}{2}(f + a)\,(L\,x - x^2) + \frac{2}{3}\frac{(f + a)}{L^2}\left(L\,x^3 - \frac{x^4}{2} - \frac{L^3\,x}{2}\right)\right] \\ &- p\left\{\frac{1}{6}\left[k\,L\left(1 - \frac{k}{2}\right)x^3 - \frac{x^4}{4}\right] - \frac{x\,L^3}{6}\left(\frac{k^4}{4} - k^3 + k^2\right)\right\} \quad \text{....(30)} \end{aligned}$$

For the deflection curve from $x = k\,L$ to $x = L$, only the p-terms change. These are: $-\,p\left[\frac{k^2}{4}L^2\left(x^2 - \frac{x^3}{3\,L}\right) - \frac{x\,L^3}{6}\left(\frac{k^4}{4} + k^2\right) + \frac{k^4\,L^4}{24}\right]$.

At the left tower the change of grade is, for this loading:

$$\begin{aligned} E\,I\tan\Delta\phi_1' = &\frac{L}{3}\left[T_1' + \frac{T_2'}{2} + H\,(f + a)\left(\frac{3\,e}{2} - 1\right)\right] \\ &+ \frac{1}{6}\,p\,k^2\,L^3\left(1 - k + \frac{k^2}{4}\right) \quad \text{.................(31a)} \end{aligned}$$

At the right tower:

$$E\,I \tan \Delta\phi_2' = -\frac{L}{3}\left[\frac{T'}{2} + T_2' + H\,(f + a)\left(\frac{3\,e}{2} - 1\right)\right]$$
$$+ \frac{p\,k^2}{12} L^3 \left(\frac{k^2}{2} - 1\right) \ldots\ldots\ldots\ldots\ldots\ldots (31b)$$

For full main-span loading and without load on the side spans ($k = 1$, and $T_1' = T_2'$), the deflection at the center of span, where $x = \frac{L}{2}$, is found from the general equation (Eq. 30):

$$\frac{8\,E\,I}{L^2}\,\Delta f = T_1' + \frac{5}{48}\,p\,L^2 + H\,(f + a)\left(e - \frac{5}{6}\right) \ldots\ldots (32a)$$

The deflection under a concentrated load at the center of the main span may be written from the previous formula by changing simply the deflection coefficient of the independent simple beam:

$$\frac{8\,E\,I}{L^2}\,\Delta f = T_1' + \frac{P\,L}{6} + H\,(f + a)\left(e - \frac{5}{6}\right) \ldots\ldots\ldots (32b)$$

The formulas for deflection and load in the side span are most easily obtained by substituting for $T_1 = 0$ in those of the main span. For a uniformly distributed load extending a distance $k_1\,L_1$ from the free end of the span:

$$E\,I_1\,\eta_1 = \frac{-T_1'}{6\,L_1}\,(x_1^3 - L_1^2\,x_1)$$
$$+ H\left[\frac{-e}{6\,L_1}\,(f + a)\,(x_1^3 - L_1^2\,x_1) + \frac{2}{3}\left(\frac{f_1 + a_1}{L_1^2}\right)\left(L_1\,x_1^3 - \frac{x_1^4}{2} - \frac{L_1^3\,x_1}{2}\right)\right]$$
$$- p_1\left\{\frac{1}{6}\left[k_1\,L_1\left(1 - \frac{k_1}{2}\right)x_1^3 - \frac{x_1^4}{4}\right] + \frac{x_1\,L_1^3}{6}\left(\frac{k_1^4}{4} - k_1^3 + k_1^2\right)\right\} \ldots (33a)$$

The change of grade at the free end of the side span is:

$$E\,I_1 \tan \Delta\phi_1' = \frac{L_1}{3}\left\{\frac{T_1'}{2} + H\left[\frac{e}{2}\,(f + a) - (f_1 + a_1)\right]\right\}$$
$$+ \frac{p_1\,k_1^2}{6}\,L_1^3\left(1 - k_1 + \frac{k_1^2}{4}\right) \ldots\ldots\ldots\ldots\ldots (33b)$$

At the tower:

$$E\,I_1 \tan \Delta\phi_1' = -\frac{L_1}{3}\left\{T_1' + H\left[e\,(f + a) - (f_1 + a_1)\right]\right\}$$
$$+ \frac{p_1}{12}\,k_1^2\,L_1^3\left(\frac{k_1^2}{2} - 1\right) \ldots\ldots\ldots\ldots\ldots (33c)$$

The deflection at the center of the fully loaded side span is:

$$\frac{16\,E\,I_1}{L_1^2}\,\Delta f_1 = T_1' + \frac{5}{24}\,p_1\,L_1^2 + H\left[e\,(f + a) - \frac{5}{3}\,(f_1 + a_1)\right] \ldots (33d)$$

For a central concentrated load, as in the main span, $\frac{P_1 L_1}{3}$ should be written in place of $\frac{5}{24} p_1 L_1^2$ in Eq. 33*d*. Eqs. 27 to 33, with the p-terms made equal to zero, are those for the deflection of spans unloaded themselves, which are influenced by the loading in other spans through the action of girder continuity and cable effect. For girders hinged at the points of support, the continuity terms are made equal to zero in these and all formulas previously derived for continuous girders. For bridges with unloaded side-span cables, f_1 is made equal to zero in Eqs. 3 to 33.

STRESSES

The formula for cable stress is the same as that for the externally-anchored bridge. Therefore the stress at any point in the cable from the combination of dead and live load is $(H_w + H) \sec \phi$, in which the angle ϕ is defined by $\tan \phi = \tan \alpha + \frac{4f}{L^2}(L - 2x)$. The influence of deflection on the cable angle ϕ, as well as on the girder angle ϕ', is negligible in its effect on both cable and girder stresses.

Since the girder, in helping to carry the dead load of the bridge, is ordinarily subject to no moment or normal shear, the only dead-load stress that it must be designed to sustain is the direct compression that amounts to $H_w \sec \phi'$ at any point. This stress is comparable to the dead-load stress in the cable.

Live-load girder stresses are those of direct compression, moment, and shear. The stresses from direct compression and moment about the axis of the girder may be treated, as in the arch, by finding, at each section examined along the girder, the combined compressive stress and the resultant tensile stress corresponding to the moments alone about the proper kern points, which are distant $\frac{r^2}{c_{U,L}}$ from the neutral axis.[6] The final flange stresses are $f_{U,L} = M_{U,L} \frac{c_{U,L}}{I}$. Therefore, influence lines for flange stress may be obtained by determining the values of the moments about the kern points for unit live-load concentrations along the bridge. This method of obtaining influence lines for girder stress is used by some German writers.[7]

The kern moments may be determined either analytically or graphically. Analytically, they are equal to the moment previously found about the geometrical girder axis (on which lie the cable reaction pins at the span ends) corrected for the effect of the components of H and V acting through the lever arms $\frac{r^2}{c_{U,L}} \mp h$. Thus in Fig. 5:

$$M_{U,L} = M \pm [V \sin \phi' + H \cos \phi'] \left(\frac{r^2}{c_{U,L}} \mp h \right) \ldots\ldots\ldots (34)$$

in which

$$\phi' = \tan^{-1} \left[\tan \theta + \frac{4a}{L^2}(L - 2x) \right] \ldots\ldots\ldots\ldots\ldots (35)$$

The kern points shown in Fig. 5 for the upper and lower flanges are $K_{U,L}$.

---

[7] "The Second Fixed Bridge Over the Rhine at Cologne," by W. Dietz, *Zeitschrift des Vereines Deutscher Ingenieure*, 1920.

Eq. 34 might also be written:

$$M_{U,L} = (T' + M_0)_{U,L} + H\,[e'\,(f + a)_m - (y + z)]_{U,L}$$
$$\pm H\left(\frac{r^2}{c_{U,L}} \mp h\right)\cos\phi' \ldots\ldots\ldots\ldots\ldots\ldots\ldots(36)$$

The influence of the component of V in Eq. 34 is included in Eq. 35 by writing the values of $(T' + M_0)$ and $H\,[e'\,(f + a)_m - (y + z)]$ directly with respect to the kern points; or, in other words, as in the definition, by taking moments directly about the kern points. This can be done more easily graphically than analytically, however. Fig. 6 shows the method of determining graphically the value of $\frac{M_{U,L}}{H}$ at any section for a unit load at a given point. The equilibrium polygons for $-(y + z)$, $e'\,(f + a)_m$, $\frac{T'}{H}$, and $\frac{M_0}{H}$ are added graphically, and the $\frac{M_{U,L}}{H}$-intercept can then be scaled from points distant $\pm\left(\frac{r^2}{c} \mp h\right)\cos\phi'$, from points on the $(y + z)$-line directly over or under the kern points of the girder. The case given in Fig. 6 is that of a symmetrical three-span bridge, with a girder (symmetrical top and bottom) that lies on a straight grade line

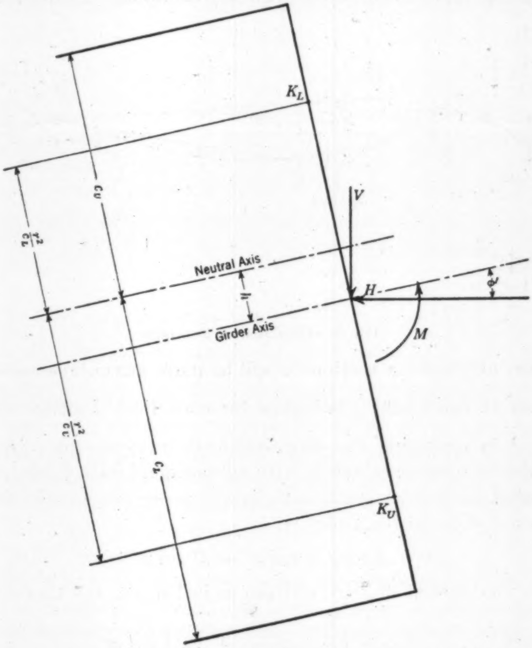

FIG. 5

in the side spans, loaded with concentrated loads in the main span and left side span. It will be noted that it is necessary to redraw only the $\frac{T'}{H}$-polygon and $\frac{M_0}{H}$-polygon for the various loads, since the other polygons remain unchanged.

Ordinarily, the shearing stresses in the girder will be small, and therefore it should be necessary to determine the shear merely at a few critical sections to test the adequacy of the web, to estimate the maximum permissible rivet and stiffener spacing, and to compute the girder reactions. To draw the influence lines for shear at these few sections it will be more advantageous to draw them directly than to construct $\frac{V}{H}$-polygons for each load position similar to the method used in obtaining the stress-moment influence-line ordinates. The latter can also be obtained directly with advantage if only a few sections are to be investigated.

FIG. 6.—EQUILIBRIUM POLYGONS

The normal shear in the girder is:

$$V_N = V \cos \phi' - H \sin \phi' \quad \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

in which V, the vertical shear, is written as in Eq. 13, and therefore:

$$V_N = \left(\frac{T_2' - T_1'}{L} + V_0 \right) \cos \phi'$$

$$- H \left[4 \left(\frac{f + a}{L^2} \right) (L - 2\,x) - (f + a)_m \left(\frac{e_2 - e_1}{L} \right) + \tan \phi' \right] \cos \phi' \quad \ldots (38a)$$

To construct the influence line, this equation may be rewritten in the following form:

$$\frac{V_N \sec \phi'}{\left[4 \left(\frac{f + a}{L^2} \right) (L - 2\,x) - (f + a)_m \left(\frac{e_2 - e_1}{L} \right) + \tan \phi' \right]}$$

$$= \frac{\left(\frac{T_2' - T_1'}{L} + V_0 \right)}{\left[4 \left(\frac{f + a}{L^2} \right) (L - 2\,x) - (f + a)_m \left(\frac{e_2 - e_1}{L} \right) + \tan \phi' \right]} - H \quad \ldots (38b)$$

EFFECT OF MOTION OF ENDS OF GIRDER DUE TO DEFLECTION OF BRIDGE

Due, principally, to vertical deflection in the main spans, the ends of the girder will move horizontally to produce a change in H from that evaluated by the elastic theory. This change in H can be determined best by successive trials from the values of the main-span deflection calculated for the new values of H. The change in H may be written

$$\Delta H = \pm \frac{\Delta x}{D} \qquad (39a)$$

in which $\pm \Delta x$ is the entire change in horizontal length of girder.

$$\Delta H = \pm \frac{3 \, \Delta x \, E \, I}{(f + a)^2 \, D' \, L} \qquad (39b)$$

In some cases this correction in H amounts to several per cent—with corresponding percentages of correction in moment. The moment corrections will be greater for load in the main span and less for load in the side span, but generally are not great enough to affect the design, although they should be considered in analyzing the motion of the structure during erection.

EFFECT OF VARIABLE GIRDER MOMENT OF INERTIA

Although the integrations required for the determination of N and D in the H-formula (Eq. 14) may be performed for varying girder moment of inertia, as in arch analysis, the value of H is usually little affected by variation in I within the span. The values of the moments, of course, are more greatly affected by the variation in I. To account for this effect the values of T' and e' corresponding to such variation can be computed by the moment-area or a comparable method and the results used in combination with the H obtained for constant I. Where constant-depth girders are used in short spans, the moment of inertia will tend to be fairly constant since it is impracticable actually to follow the moment curve closely in selecting the girder sections; and therefore the assumption of a uniform average I within the span will usually yield sufficiently accurate results.

EFFECT OF SUSPENDER ELONGATION

Analysis by the usual procedure to consider the effect of suspender elongation indicates that this action produces a negligible change in the values of moment, shear, and deflection of the girder from those computed neglecting this effect.

UNSYMMETRICAL AND MULTIPLE SPANS

The formulas for unsymmetrical three-span or multiple-span bridges require different values of the continuity terms e' and T' from those of the symmetrical three-span bridge. The changed values of e' and T' result in modification of N and D in the H-equation and of the expressions for shear, moment, and deflection. The formulas for dead load, however, are unchanged. The form of all the equations for bridges with girders hinged at the towers remains unchanged from the form of the equations of the three-span symmetrical bridge, since the girder continuity terms e' and T' become zero for the hinged condition.

COMPUTATIONS FOR A SELF-ANCHORED SUSPENSION BRIDGE WITH A CONTINUOUS STIFFENING GIRDER

A bridge with a 20-ft roadway, two 2-ft walkways, and a lightweight floor designed for H-15 highway loading is examined. The structure is symmetrical, with a 350-ft main span and two 150-ft side spans on 5% grades. The dead-load cable sag is 35 ft, and the parabolic camber of the main-span floor and girder is 4.38 ft. The open cable is made up of nine twisted wire strands, and single 36-in. wide flange beams are used for the stiffening girder.

Span and Load Constants.—Let $L = 350$ ft; $L_1 = 150$ ft; $f = 35$ ft; $n = 0.10$; $a = 4.38$ ft; and $n' = 0.1125$. The dead loads are: $w = 1{,}330$ lb per ft, and $w_1 = 1{,}430$ lb per ft; and the live load is $p = 500$ lb per ft (all loads are for one girder). For the cable, $E_c = 25{,}000{,}000$ lb per sq in.; and, for the girder, $E = 29{,}000{,}000$ lb per sq in. The dead load (see Eq. 1b) is: $H_w = \frac{1{,}330 \times 350^2}{8(35 + 4.38)}$ $= 517$ kips; the side-span cable sag (Eq. 4a) is $f_1 = \frac{1{,}430 \times 150^2}{1{,}330 \times 350^2} \times 39.38$ $= 7.82$ ft; $L_s = 743$ ft; $L_s' = 651$ ft; $I = 15{,}625$ in.^{4}; $I_1 = 21{,}175$ in.^{4}; the area of the cable is $A_c = 12.1$ sq in.; of the main-span girder, $A_g = 70.3$ sq in.; of the side-span girder, $A_{g1} = 86.1$ sq in.; $i = 0.738$; $r = 0.429$; $v' = 0.199$; $e = 0.585$; and $D' = 0.444$.

Live Load—Spans Fully Loaded.—With the main span fully loaded (Eq. 24b) $H = \frac{500 \times 350}{0.444 \times 0.1125}\left(0.20 - \frac{0.585}{4}\right) = 189$ kips; and $T_1' = \frac{-500 \times 350^2}{4 \times 3.632}$ $= -4{,}215$ kip-ft. By Eq. 32a: $\frac{8 \times 29{,}000 \times 15{,}625}{350^2 \times 144} \times \Delta f = -4{,}215 + \frac{5}{48}$ $\times 500\,(350)^2 + 189 \times 39.38\,(0.585 - 0.833)$; or $\Delta f = +1.58$ ft. The live load camber equals $a - \Delta f = 2.80$ ft.

To obtain the correction in H due to the movement of the ends of the girder corresponding to the change in camber: $\Delta L' = \frac{8}{3}(4.38^2 - 2.80^2)\frac{1}{350} = +0.087$ as a parabola; and $\frac{16 \times 29{,}000 \times 21{,}175}{150^2 \times 144}\Delta f_1 = -4{,}215 + 189\,(0.585 \times 39.38$ $- 1.667 \times 7.82)$. That is, $\Delta f_1 = -0.77$ ft; $\Delta L' = \frac{8}{3}(0.77)^2 \times \frac{2}{150} = -0.020$ ft; total $\Delta L' = +0.087 - 0.020 = +0.067 = \Delta L$ (very nearly); and (Eq. 39b) $\Delta H = \frac{+3 \times 0.067 \times 29{,}000 \times 15{,}625}{39.38^2 \times 350 \times 0.444 \times 144} = 2.6$ kips $= 1.4\%$. Furthermore, $H' = 188.5 + 2.5 = 191$ kips; $\Delta f' = +1.48$ ft; $\Delta f_1' = -0.76$ ft; the maximum stress in the side-span cable is $(517 + 191)\,1.147 = 813$ kips; the maximum direct stress in the girder is $(517 + 191)\,1.001 = 709$ kips; and (Eq. 12) the negative moment at the center of side span is: $M = -2{,}108 + 191$ $\times \left(\frac{0.585}{2} \times 39.38 - 7.82\right) = -1{,}400$ kip-ft. At the kern point: $M = -1{,}400$

-191×1.04 ft = $-1{,}600$ kip-ft. It will be noted that the effect, on the moment, of the correction in H is not important.

With the side span fully loaded (Eq. 24*b*): $H = \dfrac{0.738 \times 0.429^3}{0.444 \times 0.109} \times \left(\dfrac{0.199}{5} - \dfrac{0.585}{8}\right) 500 \times 350 = -7.0$ kips; $T_2' = \dfrac{+0.738 \times 0.429^3}{3.632 \times 1.632} \times \dfrac{500 \times 350^2}{4} = +150$ kip-ft; and $T_1' = -395$ kip-ft.

The positive moment at the center of the side span is $M = -\dfrac{395}{2} + \dfrac{500 \times 150^2}{8} - 7.0\left(\dfrac{0.585}{2} \times 39.38 - 7.82 \mp 1.04\right) = +1{,}190$ kip-ft; and, with far side span loaded: $M = \dfrac{+150}{2} - 7.0\left(\dfrac{0.585}{2} \times 39.38 - 7.82 \mp 1.04\right) = +55$ kip-ft.

Influence Line Solution for Live-Load Girder Flange Stress.—The influence-line values for H are as follows: With a load in the main span—

$$H = \frac{1}{0.444 \times 0.1125}\left[B(k) - \frac{3}{2} \times 0.585\, k\,(1 - k)\right] \ldots\ldots (40a)$$

and with a load in the side span—

$$H = \frac{0.738\,(0.429)^2}{0.444 \times 0.1125}\left[0.199\, B(k_1) - \frac{0.585}{2} k_1 (1 - k_1^2)\right] \ldots (40b)$$

TABLE 1.—COMPUTATIONS FOR INFLUENCE LINES

0.4	0.0591	0.0983	−0.0392	−0.1060	36.0	−340	− 7.05	66.5	+2.68	−25.3
0.6	0.0591	0.1123	−0.0532	−0.1440	36.0	−250	− 8.05	55.9	+3.06	−21.2
0.8	0.0369	0.0842	−0.0473	−0.1280	24.0	−187.5	− 6.05	47.2	+2.30	−18.0

The computations are given in Table 1. To simplify typography in Table 1(*a*), Eqs. 40 may be written

$$H = X\,(Y - Z) \ldots\ldots\ldots\ldots (41)$$

the proper quantities being substituted from Eq. 40*a* in the case of main-span computations and Eq. 40*b* in the case of side-span computations.

As previously explained the value of $e' (f + a) m - (y + z)$ is laid out from the center line of the girder on the elevation of the bridge drawn to scale. The values of $\frac{T' + M_0}{H}$ are then plotted to the same scale for each unit load, and the intercepts between these two lines at points along the span are measured from points distant $\pm \frac{r^2}{c} \cos \phi'$ from the $(y + z)$-line. The product of these intercepts by the values of H for the respective loads are flange-stress moments for live load. Adding these moments the maximum total positive and negative flange-stress moments are obtained. The maximum live-load flange-stress moments are:

Side Span		Main Span	
Point	Stress moment (kip-ft)	Point	Stress moment (kip-ft)
0	0	1.0 (tower)	−1,190
0.2	−1,120	0.1	− 680
0.4	−1,560	0.2	+ 930
0.6	−1,525	0.3	+1,045
0.8	−1,040	0.4	+ 910
		0.5	+ 735

The total live-load flange stresses for both direct and bending stress are then obtained by dividing the foregoing moments by the section modulus of the symmetrical girder at the several points. The dead-load stress, which is direct, is added to the live-load stress to obtain the total compressive flange stress for dead and live loads.

Live-Load Shear.—The maximum live-load shears at the ends of the main and side spans may be obtained by constructing influence diagrams that consist of graphically combining the influence lines for: V_0; $\left(\frac{T_2' - T_1'}{L}\right)$; and $-H\left[4\frac{(f + a)}{L^2}(L - 2x) - (f + a)_m\left(\frac{e_2 - e_1}{L}\right) + \tan \phi'\right]$. In obtaining vertical shear, $\tan \phi'$ under the bracket is omitted. Proceeding in this manner the following values are obtained:

Span	Vertical shear (kips)	Normal shear (kips)
End of main span.	+36.2, −28.6	+36.8, −36.0
Tower end of side span.	−44.1, +41.0	−43.8, +31.8
Free end of side span.	+36.6, −39.3	+37.4, −48.1

The end shears were all determined for full-span loading except for the main-span shear from main-span loading and normal shear at the tower end of the side span for main-span loading, which was slightly increased for partial main-span loading. The influence diagram for shear at the end of the main span is shown in Fig. 7.

The lateral wind stresses in the stiffening girders for spans such as these may be neglected since they amount to less than 25% of the total dead-load plus live-load stresses. In general, the wind stresses in self-anchored suspension bridges are relatively unimportant, since span lengths are moderate, elastic theory design of the girders requires that they be comparatively stiff, and the girders must be designed to carry dead and live load thrust in addition to moment.

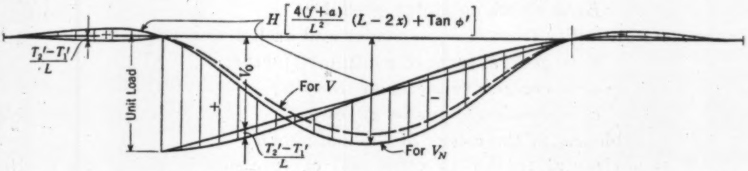

FIG. 7.—INFLUENCE DIAGRAM FOR SHEAR AT END OF MAIN SPAN

ACKNOWLEDGMENT

This paper was submitted by the author, in 1940, as a thesis to the graduate faculty of Rutgers University at New Brunswick, N. J., in partial fulfilment of the requirements for the degree of Civil Engineer.

CONCLUSION

The theory of the self-anchored suspension bridge has been presented in the foregoing in such a manner as to enable the practicing engineer readily to apply the formulas derived to the design of that type of structure. It is evident that the self-anchored suspension bridge has many advantages over other types in certain locations; and, with the theory for its design conveniently at hand, the self-anchored suspension bridge of moderate span should become widely adopted, where conditions justify its use.

APPENDIX

NOTATION

For the most part the notation in this paper (see Fig. 1) is the same as that adopted by D. B. Steinman.[5,8] An effort is made, furthermore, to conform substantially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials compiled by a Committee of the American Standards Association[9] with Society representation, and approved by the Association in 1932.

Throughout, a subscript 1 is used to distinguish side-span symbols from main-span symbols; subscript U = "upper kern point" and L = "lower kern point"; and w = "due to dead load."

A = area of cross section, the subscript c denoting "cable" and g denoting "stiffening girder";

a = center camber of stiffening girder;

---

[8] "A Generalized Deflection Theory for Suspension Bridges," by D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1135.

[9] ASA—Z10a—1932.

c = distance from the extreme fiber to the neutral axis;

D = general form of the denominator of the H-equation (Eqs. 14 and 18):

D' = working form (see Eq. 21a);

E = modulus of elasticity of girder:

E_c = elastic modulus of cable;

e = continuity factor for suspender and arch action (Eq. 10):

e' = general form of continuity factor;

e_1 = continuity factor at tower 1;

e_2 = continuity factor at tower 2;

f = cable sag at the center of the main span;

H = horizontal tension in cable and compression in girder due to live load p:

H_w = horizontal tension H due to dead load;

I = moment of inertia of stiffening girder;

i = ratio of moments of inertia, main span to side span, $\frac{I}{I_1}$;

K = a kern point;

k = ratio of span length:

$k\,L$ = a span segment;

L = main-span length:

L_s = cable length function;

L_s' = girder length function—functions defined by Eq. 17;

M = resultant bending moment at any section x of the stiffening girder:

M' = the moment in the members of the system with the cable cut;

M_w' = dead-load moment carried by the girder, as a parabolic arch;

M_0 = simple-beam bending moment due to a live load p;

M_D = simple-beam bending moment due to dead load w;

m = bending moment in the members of the system due to a unit horizontal component of cable stress;

N = numerator of H-equation (Eq. 14);

n = ratio of cable sag to span length, $\frac{f}{L}$:

$n' = \frac{f + a}{L}$;

P = concentrated load;

p = live load per unit length:

p_g = part of the live load taken by the girder in moment;

r = ratio of length of side span to main span, $\frac{L_1}{L}$;

S = direct stress in the various members of the system:

S' = direct stress in the various members of the system with the cable cut;

s = length of cable:

ds = increment of cable length;

T = bending moment at any section x due to continuity:
  T_1 = moment at tower 1;
  T_2 = moment at tower 2;
  T' = moment effect of continuity on the independent girder (cable removed); general form;
  $T_1' = T'$ at tower 1;
  $T_2' = T'$ at tower 2;
t = temperature;
u = direct stress in the members of the system, corresponding to a horizontal component of stress equal to unity in the cable and girder;
V = total vertical shear at any section x of the stiffening girder, due to live load p:
  V_N = normal shear;
  V_0 = simple-beam vertical shear due to live load;
$v = \dfrac{f_1}{f}$:
  $v' = \dfrac{f_1 + a_1}{f + a}$;
w = uniformly distributed dead load:
  w_a = part of the dead load carried by the stiffening girder as an "arch";
X = a substitution factor in Eq. 41;
x = abscissas in main span measured from the tower:
  x_1 = abscissas in the side span measured from the free end of the side span;
Y = a substitution factor in Eq. 41;
y = cable ordinate;
Z = substitution factor in Eq. 41;
z = stiffening girder ordinate;
α = slope of cable chord in any span;
Δ = increment:
  Δf = midspan deflections;
  Δy_t = vertical deflection of the girder at the towers due to temperature change;
  $\Delta\phi$ = angular deflection of cable;
  $\Delta\phi'$ = angular deflection of girder;
  Δx = change in horizontal length of girder;
η = deflection of truss at any section x;
θ = slope of the girder chord in any span;
ϕ = slope of cable at any point:
  ϕ' = slope of the girder at any point.

DISCUSSION

A. J. MEEHAN,[10] M. AM. SOC. C. E. (by letter).—As much as the suspension bridge has occupied the spotlight during recent years, the self-anchored type has not enjoyed great prominence. The complexity of its analysis, which has existed heretofore, has been one of a number of contributory factors responsible for its infrequent selection. The long-awaited "Simplified Theory of the Self-Anchored Suspension Bridge" is now at the disposal of designers, for which warm thanks are due to Mr. Gronquist.

Possibly a discussion on this paper should be confined strictly to theory. However, taking a liberal viewpoint of "theory," it may be regarded as a cog in the production of something concrete or tangible. As such, the writer submits his generalizations, prompted by the experiences of his association in the rather complete preparation of preliminary designs for two separate river crossings by self-anchored suspension bridges. These preliminaries each consisted of a main span of 480 ft. Loaded side spans on one were 165 ft each, and flanking approach spans gave an aggregate length of 1,128 ft for this project. For the other layout, side spans of 150 ft were planned, to which were added a number of approach spans, resulting in a total bridge length of 1,590 ft. Each project provided a 26-ft roadway and two cantilevered sidewalks of 4-ft clear width.

In the self-anchored group of suspension bridges are those having a combination of counterweighted anchorage pier and self-anchored side span. At the sites previously mentioned, high water conditions prohibited this construction. During flood stages, the end piers, acting as gravity anchorages, would have been submerged to such an extent that the resulting buoyancy would have seriously impaired their usefulness.

Column action may require excessive sections in the side-span stiffening girder or truss to resist the horizontal component of the cable pull. In some stiffening trusses, the lower chord takes the horizontal cable reaction. In such cases, the top chord details may become awkward in order that a direct cable connection may be made with the bottom chord.

To transmit end-span loads ideally (including lateral forces, such as wind and earthquake), it is probably more important in this type, than in any other kind of structure, to adopt a compact and effective framing arrangement. Such a requirement gives stiffening girders the advantage of selection over stiffening trusses, due to a more unified action. It is probable that a steel floor might serve as the element to carry transverse shear by web action between stiffening girders acting as flanges.

In the projects with which the writer was connected, although trusses were considered, stiffening girders were given the "decision." The stiffening girders were cambered nearly sufficient to carry the entire dead-load moment. In other words, the stiffening-girder dead-load thrust practically coincided with the neutral axis. An effort was made to carry the remainder of the moment in the floor system. Difficulty was encountered in providing enough rivets and transmitting the loading from one floor panel to the next. Excessive material was required for shear development between the floor system and the concrete slab. However, the studies included steel-floor adaptation and also an attempt to relieve some of the stiffening-girder thrust with the lateral system.

---

[10] Senior Bridge Engr., State Dept. of Public Works, Div. of Highways, Bridge Dept., Sacramento, Calif.

Except for shorter spans, the satisfactory solution of the end connection, of either parallel wire cables or wire-rope strands, to the stiffening member can become as involved as any problem in structural steel detailing. Of course, the cables or chains could be connected to points other than at the extreme end of the stiffening girder, but this adds moment and shear due to the upward component of the cable reaction.

This type of bridge is obviously penalized from a cost standpoint by additional dead load due to details whose sole purpose is to counteract eccentricity or whose function is to restrain buckling tendencies of the stiffening girders acting as columns. Of further economic concern is the handicap involved in the provision for materials required for erection purposes only, which may include temporary connections or auxiliary and jacking struts or increases in sections of the permanent members due to the excess of erection stresses over normal. Some savings might be effected by scheduling the erection procedure so that use would be made in a temporary position—during the earlier stages of erection—of some of the materials required for other positions in the finished structure.

Eyebar chains are superior to cables because of easier connections at the stiffening member ends and simpler erection connections. At present (1941) eyebar production has been curtailed due to defense needs, so that all desirable sizes are not available; but at no time have eyebars been competitive bid items since the acceptable kind have been manufactured by only one company.

Falsework costs are greater in proportion for longer spans using trusses than in shorter spans using girders. Falsework for self-anchored suspension spans must remain in place not only during steel erection, but possibly until the concrete slab has been completed. This long period tends to increase the charge for the contractor's plant, which the owner pays indirectly. In streams where floods may develop during steel erection, the hazard is obvious.

Girders are generally more economical than trusses for the stiffening members in cases of reasonable span lengths and in ordinary roadways. To date, self-anchored spans have generally been short enough to permit girders to be used in lieu of stiffening trusses. However, recent tests have revealed that, from the standpoint of aerodynamic stability, holes should be provided in the tops and bottoms of girder webs up to 25% of the web area as one means of effecting such stability. Perhaps if such an area of open space is desirable through the sides of stiffening girders, one's preference may turn to stiffening trusses. It is recognized that the aerodynamic phenomenon does not demand attention when the span-to-width ratios are low as compared to the range of tried and proved structures.

Since simplification of the theory is the author's aim, with the ultimate objective of popularizing the type, it may be well to recognize some of the further obstacles to such progress. At present there is no accepted design specification for self-anchored suspension bridges. As a consequence, such development has stagnated. What, for instance, would be the acceptable live loading for a structure financed under such circumstances? Invariably what one gets when trying to secure an advance opinion (from an agency disbursing public bridge funds—of what, for instance, would be acceptable as to live loading for a structure financed under such circumstances) is some arbitrary answer ranging up to 50% more than factual conditions may permit. More explicitly, the required value might be 60 lb per sq ft live load instead of a submitted 40 lb per sq ft. Glenn B. Woodruff and Norman C. Raab,[11] Members, Am. Soc. C. E., have demonstrated the ultraconservativeness of such a requirement. They indicate that the maximum possible vehicular live load on a suspension bridge will be obtained with traffic at a standstill (hence, without impact), and with cars placed bumper to bumper, which condition produces a live load of 35 lb per sq ft. When the load is moving slowly, it may be only 25 lb per sq ft (impact to be added).

Another case in point concerns the cable. The effect of live loading per square foot may expand the safety factor tremendously. To produce the maximum stress in the main cable, the full length of the bridge is loaded. If a safety factor of three were required for the breaking strength of the cable when stressed under full dead and live load, and if the ratio of dead-to-live load were 3 to 1, then the safety factor for the live load would attain the unreasonable value of 9.

The unsatisfactory situation with respect to secret production details of heat-treated eyebars and of processing cable wire is alike, inasmuch as the designer openly admits his dependence upon the manufacturer. To protect himself, the designer resorts to specifying minimum acceptable materials and conditions. Although secretive, the manufacturers are nevertheless cooperative.

The variations in wire-rope strand construction make it difficult to obtain an accurate forecast of the resulting modulus of elasticity after the pre-stressing operation. However, if pre-stressing is adopted, one should require that the procedure develop a stress at least equal to the maximum design stress. The fullest advantage of pre-stressing will result if, as an added precautionary measure, it is specified that the ropes are to be socketed before pre-stressing.

It seems possible that, for certain locations, skewed suspension bridges are required, although they are never seen. In view of the present National Defense demands and the attendant difficulties in securing adequate quantities of structural steel, it seems likely that the concrete tower might find application in suspension-bridge design, plastic flow of concrete and other difficulties to the contrary notwithstanding.

An effort has been made herein to summarize some of the pitfalls that the enthusiast for self-anchored suspension bridges will encounter before his dream bridge can begin to function. Personal observation of the three self-anchored suspension bridges in Pittsburgh, Pa.—at Sixth, Seventh, and Ninth streets—

---

[11] *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 614.

has demonstrated amply the practicality of such structures to the writer. It is sincerely hoped that a newly rejuvenated era of self-anchored suspension bridges will be the response to the stimulating influence of Mr. Gronquist's illuminating contribution.

C. B. McCullough,[12] M. Am. Soc. C. E. (by letter).—Little can be added to Mr. Gronquist's most able treatment of the theory of self-anchored suspension spans. His presentation is complete yet concise, and the subject matter should prove of distinct value to every designing bridge engineer.

The self-anchored type presents greater possibilities of economic utilization than are generally realized. This statement finds corroboration in the results of certain studies of short-span highway structures made by the Oregon State Highway Department in 1937 and 1938. The first phase of this latter investigation comprehended the development of designs and estimates for fifteen two-lane highway structures, each having a total length of approximately 750 ft, in groups, as follows:

Group	Type
A	Simple truss spans
B	Cantilever spans
C	Externally-anchored suspension spans (truss stiffened)
D	Self-anchored suspension spans (girder stiffened)
E	Self-anchored suspension spans (truss stiffened)

The various span lengths are given in Table 2. In the self-anchored girder-stiffened suspension spans (Group *D*) the stiffening girders were rigidly anchored to the deck by means of perforated T-bars attached to the girder webs with the deck reinforcing passing through the perforations. The deck was also anchored to the stringers by means of Z-bar connections spaced approximately 4 ft center to center. The girders and stringers, acting as a composite unit, were designed to resist the stiffening frame moment. This arrangement affords considerable economy of material and accounts, in part, for the relatively low cost of this type.

Based upon unit prices prevalent at that time (1937 and 1938), the cost per lineal foot for the various design types and span arrangement was as indicated in Fig. 8. (The general trend beyond data points is shown by broken lines.) The comparisons indicated in Fig. 8 were based upon structures having the same total length but with varying side-span ratios. Since some of the span arrangements selected were obviously uneconomical, the investigation was extended to include a comparison of structures of varying total lengths but constant side-span ratio, as indicated in Fig. 9.

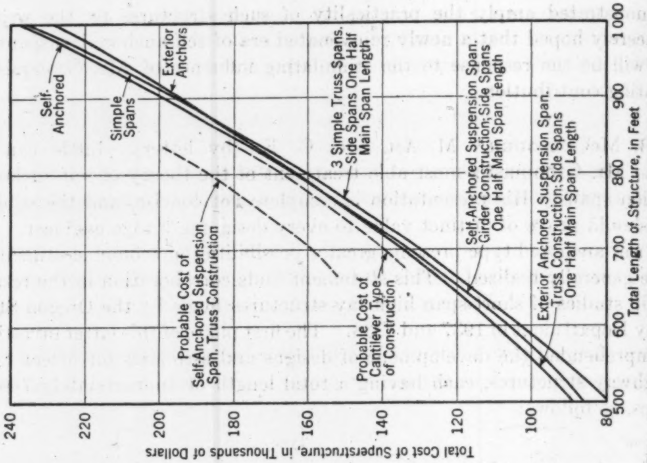

FIG. 9.—TOTAL SUPERSTRUCTURE COST FOR VARIOUS TYPES OF BRIDGES (SIDE-SPAN RATIO = 0.50; 27-FT ROADWAY; AND TWO 5-FT WALKS)

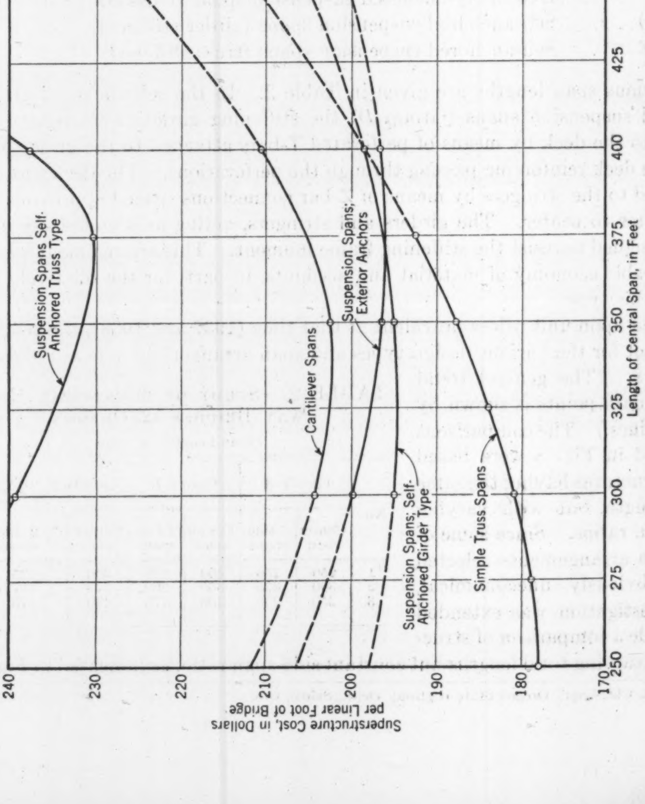

FIG. 8.—COST COMPARISONS PER LINEAL FOOT FOR THE VARIOUS COMPARATIVE TYPES

Since the cantilever type and the self-anchored suspension type using truss construction indicated no economy in the first comparison, they were not included in the second. The probable cost trends for these latter types through the central range of the diagram (Fig. 9) are indicated by dotted lines.

An inspection of Figs. 8 and 9 indicates that the self-anchored suspension design, utilizing the girder system, is quite likely to show economy in first cost for three-span arrangements in which the central span exceeds 400 ft. This is only true when the central span is the controlling factor. If it is possible to cut the central opening, the simple truss type will show economy in first cost, as indicated in Fig. 10.

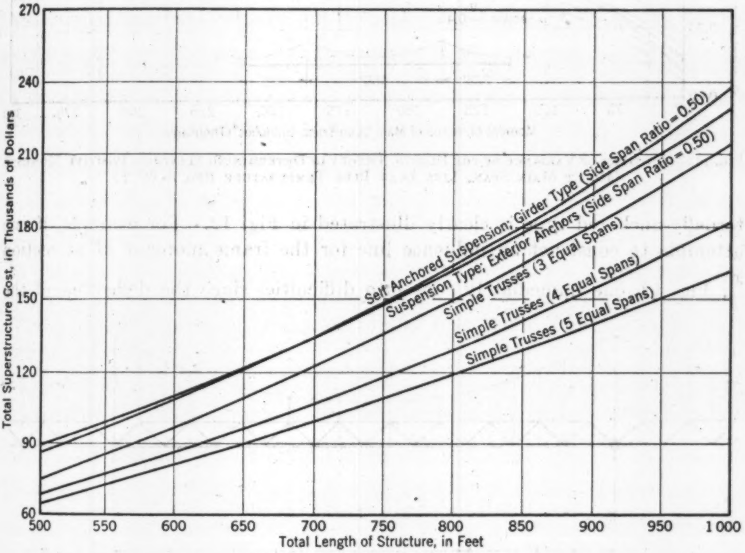

FIG. 10.—COMPARATIVE SUPERSTRUCTURE COST, SUSPENSION TYPES VERSUS SIMPLE TRUSSES

A most important property of the self-anchored suspension type is the fact that the effect of the deflection term is canceled in the moment equation so that a simplified procedure is possible in the analysis. This is nicely developed by the author in his discussion of live loads.

The effect of this deflection term is considerable even for short spans, as will be seen from an inspection of Fig. 11, which indicates the degree of variance between the exact method and the so-called elastic theory when applied to a 225–450–225 ft, externally-anchored, suspension design, for varying values of the moment of inertia of the stiffening frame. For the more flexible frames the divergence is of material magnitude and this fact (with the further fact that the degree of variance is not constant but varies from point to point along the span) renders the approximate or elastic theory of little value for externally-anchored structures.

Another important advantage in the method of analysis developed by the author for self-anchored spans is the fact that it is possible to develop and utilize influence diagrams. That such diagrams cannot be used for the externally-anchored type is clearly illustrated in Fig. 12. For example, if one attempts to construct an influence line for the frame moment M at section $\frac{x}{l}$, Fig. 12, one immediately runs into difficulties since the deflection of the cable fluctuates with the magnitude and position of the load. In other words, as a unit load moves across the span from right to left, the increasing cable deflection shifts the node point n so that the negative-moment area is a continuously fluctuating quantity dependent upon the position of the load.

FIG. 12

In summary, therefore, the self-anchored suspension type not only indicates distinct possibilities for economic utilization but also lends itself to certain simplified design procedures which are not applicable to externally-anchored designs. The author is to be congratulated for presenting, in a most readable manner, a method of analysis that should be of great benefit to the designer.

Jaroslav J. Polivka,[13] M. Am. Soc. C. E. (by letter).—A valuable contribution to the analysis of the self-anchored suspension bridge is contained in this paper. The arch-like action of the cambered girder may reduce cable and girder stresses considerably, and the economic advantage of such a structure is evident. The economy increases, naturally, with the amount of the vertical camber. Usually the vertical camber is limited by the required grade of the girder, and is relatively small in such a characteristic type of a suspension bridge as is shown in Fig. 1. In this case assumption (3) is justified—namely, that the average moment of inertia of the stiffening girder throughout each span is constant.

This assumption involves the approximation

$$\frac{\cos^2 \alpha}{\cos^3 \phi} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

in which α is the angle of the tangent at the ends and ϕ is the average angle of the structural sections of the arched girder, both with respect to the chord. The condition expressed by Eq. 42 results from the differential equation of the elastic curve,

$$E\,I \cos^3 \phi \frac{d^2\eta}{dx^2} = -M_x \ldots\ldots\ldots\ldots\ldots\ldots\ldots (43a)$$

and from equations of continuity having the form

$$\frac{\cos^2 \alpha_1}{\cos^3 \phi_1}\theta_1 + \frac{\cos^2 \alpha}{\cos^3 \phi}\theta = 0 \ldots\ldots\ldots\ldots\ldots\ldots (43b)$$

Eq. 11, representing the continuity of the independent girder, is correct for the varying moment of inertia of the cambered girder following the relationship,

$$I = \frac{I_0}{\cos \phi} \ldots\ldots (44)$$

in which I_0 is the moment of inertia of the cambered girder at the crown.

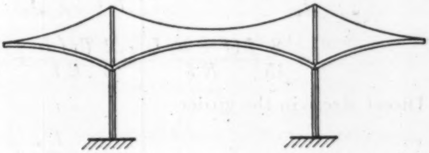

Fig. 13

The theory can be extended and applied for structures as shown in principle by Fig. 13, which represents a new type of structure of great economy, especially for large-span buildings, such as hangars, assembly plants of plane factories, etc.

WILLIAM BERTWELL,[14] ASSOC. M. AM. SOC. C. E. (by letter).—Although this paper is interesting and valuable, the method of design presented involves the use of fairly complicated formulas. The reduction of computations to substitution in formulas is often useful and desirable, but the writer believes that in this instance a more flexible procedure is preferable.

A clear conception of the action of the structure is obtained through consideration of the geometry of its deflections. If the cable is cut at one connection to the stiffening girder, a unit horizontal tension applied to the cable, and a unit horizontal compression applied to the girder, then the vertical deflections of the girder, divided by the relative horizontal movement of the girder and cable at the cut, yield the influence line for the horizontal component of cable stress. Although this well-known principle is expressed by Eq. 14, the writer believes that if the indicated steps are performed independently the possibility of overlooking a structural peculiarity of a given bridge is minimized, and the work is often simpler. The use of a truss or a girder with varying moment of inertia then results in no more difficulty than in an ordinary continuous structure without a cable.

It also appears that, if the points of actual suspension are chosen for the computation of influence ordinates, the effects of distributed loads might well be determined from those ordinates, rather than by integrations, which assume a continuous supporting medium.

Adopting the author's numerical example, the work would proceed about as follows in determining the influence line for H: The vertical load on the girder is $\frac{8\,(f + a)}{L^2} = -\,0.00278$ lb per ft in the side spans, and $-\,0.002571$ lb per ft in the main span. The moment at the tower may be determined by moment distribution, for example, and is 23.041 lb-ft.

The relative horizontal movement of the cut ends is:
Direct stress in the cable—

$$\frac{L_s}{A_c\,E_c}.$$

Bending in the cable—

$$\int_0^L (y + z + T_1)\,y\,\frac{dx}{E\,I} + 2\int_0^{L_1}\left(y_1 + T_1\,\frac{x_1}{L_1}\right)y_1\,\frac{dx_1}{E\,I_1}$$

$$= \frac{8}{15}\,\frac{f\,(f + a)\,L}{E\,I} + \frac{2}{3}\,\frac{T_1\,f\,L}{E\,I} + \frac{16}{15}\,\frac{f_1^2\,L_1}{E\,I_1} + \frac{2}{3}\,\frac{f_1\,L_1\,T_1}{E\,I_1}.$$

Direct stress in the girder—

$$\frac{L'_s}{A_g\,E}.$$

Bending in the girder—

$$\int_0^L (y + z + T_1)\,z\,\frac{dx}{E\,I} = \frac{8}{15}\,\frac{(f + a)\,a\,L}{E\,I} + \frac{2}{3}\,\frac{T_1\,a\,L}{E\,I}.$$

---

[14] Structural Engr., Public Roads Administration, San Francisco, Calif.

Totaling these terms:

$$\frac{L_s}{A_c\,E_c} + \frac{L'_s}{A_g\,E} + \frac{8}{15}\,\frac{(f + a)^2\,L}{E\,I} + \frac{2}{3}\,T_1\,\frac{(f + a)\,L}{E\,I} + \frac{16}{15}\,\frac{f^2_1\,L_1}{E\,I_1} + \frac{2}{3}\,\frac{f_1\,L_1\,T_1}{E\,I_1}$$

$$= \frac{144}{29 \times 10^6}\,(0.49465 + 0.05890 + 18.52200 - 13.54811$$

$$+ 0.46207 - 0.85091) = 5.1386\,\frac{144}{29 \times 10^6}.$$

TABLE 3.—INFLUENCE ORDINATES FOR *H*

Description	Fraction of Side Span				Fraction of Main Span				
	0.2	0.4	0.6	0.8	0.1	0.2	0.3	0.4	0.5
Vertical deflections[a]	−0.2694	−0.5467	−0.7426	−0.6611	1.9656	4.6469	7.1795	8.9460	9.5761
Influence Ordinate for *H*..	−0.0524	−0.1064	−0.1445	−0.1287	0.3825	0.9043	1.3972	1.7410	1.8636

[a] Multiplied by $\frac{29 \times 10^6}{144}$.

The vertical deflections of the girder may be computed by any method the designer prefers. Table 3 shows the vertical deflections $\left(\text{multiplied by } \frac{29 \times 10^6}{144}\right)$ of the girder, and the influence ordinates for *H*, which are obtained by dividing by 5.1386.

It is not clear to the writer what the author includes in his correction of *H*. He states (see heading "Effect of Motion of Ends of Girder Due to Deflection of Bridge") that Δx is the "entire change in horizontal length of girder." The computation he indicates in his numerical example appears to bear out this definition. However, the writer believes that if this simple interpretation is intended the author has overlooked the fact that the elastic theory determines *H* by computing, among other values, the change in horizontal length of girder. The error in the elastic theory arises from the fact that deflections change the arms by which angle changes are multiplied to obtain horizontal movements. This error is greatest for the condition of a heavy load in the main span only, which results in deflections that are large compared to the camber of the girder and the sag of the cable. The error will be the difference between the change in horizontal length calculated by the elastic theory, and that which actually occurs. If this correction is made, it should not be limited to consideration of the girder only, as the cable contributes appreciably, particularly in side spans where the sag is small. Using the author's example, for the case of a 500-lb uniform load in the main span only, the value of *H* was found to be

TABLE 4.—CHANGES IN HORIZONTAL LENGTH CAUSED BY BENDING

Member	Elastic Theory		Actual	
	Main span	Side spans	Main span	Side spans
Cable...	−0.8240	+0.4096	−0.8288	+0.3237
Girder..	+0.1030	0	+0.0865	−0.0210

188,210 lb; the deflection at the center line of the main span was 1.5847 ft; the deflection at the center line of the side spans was − 0.769 ft; and the changes in horizontal length were as shown in Table 4.

Both the cable and girder are actually shorter than is indicated by the elastic theory. (The changes in horizontal length caused by direct stress, which are in addition to those shown in Table 4, are a lengthening of 0.4623 ft for the cable and a shortening of 0.0551 ft for the girder.) The correction in H will be: $\frac{0.0907 - 0.0375}{5.1386} \times \frac{29 \times 10^6}{144} = 2{,}080$ lb. Although this value is not much different from that determined by the author, it would appear that this is a coincidence, and not a result to be expected generally.

A. A. Eremin,[15] Assoc. M. Am. Soc. C. E. (by letter).—A simplified method of analyzing stresses in a self-anchored suspension bridge is presented in this paper. The computations serve to illustrate its simplicity.

It may be of interest to determine the error that may be introduced due to the simplifying assumptions adopted. The author assumed that the moment of inertia of a stiffening girder is constant for the entire length of the girder in each span. Prof. G. G. Krivoshein computed the stresses in a self-anchored suspension bridge with a continuous girder, assuming a constant moment of inertia in the girders and a varying moment of inertia increasing toward the supports. He found that the error due to neglecting the variation of moment of inertia may be more than 15%, and he stated that the method with the constant moment of inertia cannot generally yield suitable results.[16]

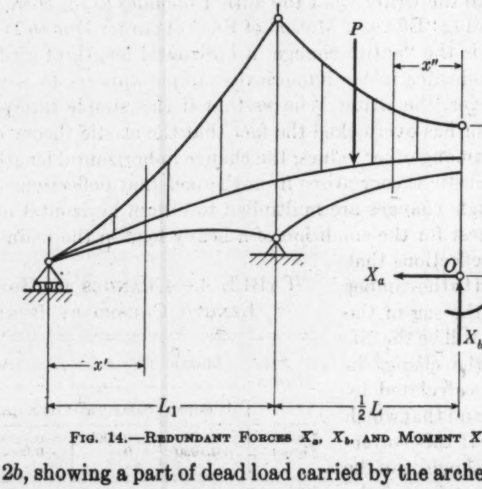

Fig. 14.—Redundant Forces X_a, X_b, and Moment X_c

In Eq. 2b, showing a part of dead load carried by the arched stiffening girder, the author has neglected the effect of bending stresses on the amount of dead or live load carried by the arched girder. Evidently, this effect varies in direct proportion to the arch rise.

---

[15] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[16] "Simplified Calculation of Statically Indeterminate Bridges," by G. G. Krivoshein, Prague, 1930, p. 204.

The author has shown that the elastic theory applied to the analysis of stresses in a self-anchored suspension bridge gives satisfactory results. In his analysis of stresses in a self-anchored bridge, Professor Krivoshein applied the theory of elasticity,[16] with similar results, using the same method as that adopted for the analysis of stresses in an arch bridge. He severed the suspension bridge at the center of the middle span and replaced the removed half bridge by three redundant stresses: X_a, a horizontal force; X_b, a vertical shear; and X_c, a bending moment (see Fig. 14), as follows:

$$X_a = -\frac{\int M_q\, M_a \frac{1}{I}\, dx}{\int M^2{}_a \frac{1}{I}\, dx + \int S^2{}_o \frac{1}{A_o}\, dx + \sum S^2{}_c\, s \frac{1}{A_c}} \ldots\ldots\ldots (45a)$$

$$X_b = -\frac{\int M_q\, M_b \frac{1}{I}\, dx}{\int M^2{}_b \frac{1}{I}\, dx} \ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

$$X_c = -\frac{\int M_q\, M_c \frac{1}{I}\, dx}{\int M^2{}_c \frac{1}{I}\, dx} \ldots\ldots\ldots\ldots\ldots\ldots (45c)$$

and

$$d = \frac{\frac{1}{L_1}\int_0^{L_1} z\, x' \frac{1}{I}\, dx' + \int_0^{\frac{L}{2}} z \frac{1}{I}\, dx'}{\frac{1}{L^2{}_1}\int_0^{L_1} (x')^2 \frac{1}{I}\, dx' + \int_0^{\frac{L}{2}} \frac{1}{I}\, dx''} \ldots\ldots\ldots\ldots (46)$$

in which (in addition to the notation of the paper): M_q = moment at any section of the main statically determinate system (see Fig. 14), resulting from the given external loading P only (X_a, X_b, and X_c being removed); M_a = moment at any section of the main statically determinate system due to loading $X_a = 1$ (all other loads being removed); M_b = moment at any section of the main statically determinate system due to loading $X_b = 1$ (all other loads being removed); M_c = moment at any section of the main statically determinate system due to loading $X_c = 1$ (all other loads being removed); and d = length of stiff arm to which forces X_a, X_b, and X_c applied.

Evidently each redundant force for a given loading may be computed directly, and the influence lines for stresses may be constructed by Eq. 45.

Unlike the formulas in the paper, Eq. 45 cannot be reduced for application to an externally-anchored suspension bridge. This agrees with the author's statement that the self-anchored bridge acts more like a tied arch than an externally-anchored suspension bridge. It is to be noted that the elastic and geometrical qualities of the self-anchored bridge are considered more directly in Eq. 45. However, the author's method of analysis is more simple and requires less time for computation.

C. H. GRONQUIST,[17] ASSOC. M. AM. SOC. C. E.—The discussions have added greatly to the value of the paper. The presentation of alternative methods of analysis, although leading to the same results, serves to indicate the advantages and disadvantages of the simplified method, and gives the reader a proper perspective of the problem of analyzing the structure. Study of the practical phases of the design of the self-anchored suspension bridge, and economic comparisons with other types of structures, serve to complete the picture.

That the self-anchored suspension bridge is a type of structure which ordinarily will not be used except where conditions are particularly suitable is excellently stated by Mr. Meehan in his thorough discussion of the practical aspects of the subject. There are many locations, however, where the type is eminently suitable, as shown in the paper, and recognition of the fact will undoubtedly lead to the wider adoption of the self-anchored suspension bridge as the proper solution of many moderate-span crossing problems.

The difficulties attendant on the design and construction of the self-anchored suspension bridge appear in several instances to have been overemphasized by Mr. Meehan. Design of the stiffening girders to take compression usually does not require an excessive amount of material, considering that the foundations are lightened, since vertically the live-load bending moments require a stiff section, and lateral support can be obtained at close intervals either from the floor or from an adequate system of lateral bracing. While the details of the cable connection to the girder are somewhat troublesome for longer spans, they can be handled without much difficulty for spans up to 600 ft. Probably for the longer spans it is well to avoid great eccentricity in this connection, although for shorter spans the additional material required to connect the cable and girder above the latter will not be sufficient to offset some practical advantages in so doing. Connection of a wire-rope-strand cable to the girder is made with little more difficulty than for an eyebar cable, as it merely involves the transition from the wire cable to the anchor plates that connect directly to the girder in the same manner as for eyebars.

Erection of the self-anchored suspension bridge is usually done by means of falsework. The eyebar cable spans in Pittsburgh were erected by the cantilever method, however, and erection of wire-cable spans by use of temporary external anchorage to eliminate the falsework has been proposed also. Mr. Meehan states that erection stresses necessitate increase in the section of the stiffening girder or truss members, but this need not be so if the falsework bents are moderately spaced. Moreover, it is not necessary to keep the bridge on falsework after the girders, floor beams, and laterals have been erected, as it usually will be easier to make the cable-to-girder connection at that time rather than later when all dead load is on the structure. This procedure was used on the recently completed Wabash River Bridge (Illinois-Indiana), as well as on many others.

---

[17] Assoc. Engr., Robinson & Steinman, New York, N. Y.

As stated by Mr. Meehan, girders, in a great many respects, have an advantage over trusses for use as the stiffening member of the self-anchored suspension bridge. The girder has exhibited undesirable aerodynamic characteristics in light externally-anchored suspension bridges, but this objection to the girder as the stiffening member does not appear to be valid in the case of the self-anchored suspension bridge. Inasmuch as the girder in the latter case must be designed in accordance with the requirements of the elastic theory, which was likewise pointed out by Mr. McCullough, and since it must be stiff enough also to carry the dead-load and live-load direct compression, the self-anchored suspension bridge invariably will be a relatively stiff structure.

As a means of comparing the vertical stiffness of suspension bridges, a constant may be derived from the deflection formula for simple beams under fully distributed loads. Assuming half-span loading, which would produce contraflexure near the center of the main span, such a constant might be written:

$$C = \frac{1}{L^2}\left(H_w + 4 \times \frac{9.6\,E\,I}{L^2}\right) \dots\dots\dots\dots\dots\dots (47)$$

For the self-anchored suspension bridge, the term H_w will not appear, as the cable stress does not contribute to stiffness in the "closed" structure that is analyzed properly by the elastic theory. Even with the girder producing the entire stiffness of the system, however, the value of this constant for self-anchored suspension bridges proves to be relatively high and, where in addition the stiffening girders are made continuous, further stiffening is produced.

Mr. Meehan mentions the possibility of using concrete towers as a substitute for the steel towers of suspension bridges. Although it is not applicable necessarily to the self-anchored type, it is of interest to note the use of fixed-base concrete towers on short suspension spans with unloaded side-span cables in Northern Sweden in recent years, apparently with successful results.

In making preliminary designs for self-anchored suspension bridges for which he made studies, Mr. Meehan states that it was not possible to camber the girders sufficiently to eliminate all dead-load moment. Unless eccentric details are used, there will be no dead-load moment in the stiffening girders of the self-anchored as well as the externally-anchored suspension bridge, with suspended side spans, so long as the cables, girders, and suspenders are cut, fabricated, and erected to proper length and elevation for the stress condition existing at the time of the various operations computed back from the dead-load or normal position.

The discussion by Mr. McCullough makes a distinct contribution to the paper in presenting in graphic form economic comparisons between the self-anchored suspension bridge and the simple span and cantilever, as well as the externally-anchored suspension bridge, for varying lengths of span and total length of structure. His conclusions confirm the more general observations of the writer. Structural connection of the steel floor system and concrete roadway slab to the stiffening girder to take advantage of the natural tendency of the former two to participate with the girder in reacting against the pull of the cable and stiffening the structure, used in the studies by Mr. McCullough, accounts partly for the economy secured with the self-anchored suspension type. Some of the details required to obtain complete interaction of the floor and girder are likely to be rather complicated; but this interaction is a definite characteristic of the self-anchored suspension bridge, as of the tied arch, and the savings to be made by recognition and proper exploitation of the fact should not be lost sight of by the designer.

The remarks of Messrs. Polivka and Eremin in regard to the effect of variable moment of inertia of the stiffening girder are of interest. Where girders of varying depth, which increases toward the towers, are used, it is to be expected that moments obtained on the assumption of constant moment of inertia will be considerably in error, and the simplified method of analysis should be modified in such cases, as outlined in the paper. Where the stiffening girders are of constant depth, even though the moment of inertia varies, the simplified method should prove sufficiently accurate. While the formulas presented would not apply directly to the structure described by Mr. Polivka and shown in Fig. 13, the same general method of approach undoubtedly could be used to advantage in its analysis.

The writer agrees with Mr. Bertwell that it is well not to rely entirely on formulas for the analysis of indeterminate structures. His discussion explains clearly the geometrical basis for the solution of the self-anchored suspension bridge, and constitutes a valuable addition to the paper.

The formulas for D, the denominator of the H-equation, can be simplified somewhat, as was the formula for N, the numerator of the H-equation, by recognition of the fact that, in computing the deflection of an indeterminate structure by the method of the dummy unit load, the value of m, or the moment produced by the unit load, may be taken for a statically determinate condition, and that therefore in this case

$$\int_0^L \left[e'(f + a)_m - (y + z) \right] e'(f + a)_m \frac{dx}{E\,I} = 0 \ldots\ldots\ldots (48)$$

The value of D then may be written (compare Eq. 18b):

$$D = \frac{(f + a)^2 L}{3\,E\,I} \left[\left(\frac{8}{5} - 2\,e \right) - 2\,i\,r\,v' \left(\frac{8}{5} v' - e \right) + \frac{3\,I}{(f + a)^2 L} \left(\frac{E}{E_c} \times \frac{L_s}{A_c} + \frac{L'_s}{A_g} \right) \right] \ldots\ldots\ldots\ldots (49)$$

The formula for the denominator of the H-equation when stated in this form agrees with that of Mr. Bertwell.

As stated by Mr. Bertwell, the method of correcting the value of H for the effect of deflection requires modification. The change in horizontal span of cable or girder may be written:

$$\Delta L = \frac{8}{3 \sec^4 \alpha} \left[\frac{f^2}{L} - \frac{(f + \Delta f)^2}{(L + \Delta L)} \right] + \Delta L_d \text{ (very nearly)} \ldots\ldots (50a)$$

in which ΔL_d is the change in length, not span, due to direct stress, and equals:

$$\Delta L_d = \frac{H\,L}{E\,A}\left(\sec\alpha + \frac{8\,n^2}{3\sec^3\alpha}\right)^2 \quad \text{(50b)}$$

The sum of the changes of span of the cable must equal the sum of the changes of span of the girder, obtained by substitution in the foregoing formulas of the deflections Δf and the value of H given by the elastic theory. The correction in H therefore may be computed by substitution in Eq. 39*b* of the amount by which these changes in span fail to agree. The amount of the correction of both H and moment is negligible, although that of deflection is not, as already indicated in the computations of the paper. The use of the factor 2.6 in place of $\frac{8}{3}$ in Eq. 50*a* will give more accurate results for change of span of main-span cable. The correction in the H of the numerical example of the paper, obtained in this manner, would be little changed from that originally given. The writer believes that the 2.08-kip change in H computed by Mr. Bertwell is not correct, since the total actual changes in span of cable and girder, as given, do not agree.

Mr. Eremin states that the effect of bending stresses on the amount of dead or live load carried by the arched girder has been neglected in deriving Eq. 2*b*. For the type of self-anchored bridge considered in this paper—that is, the bridge with a suspended side span—there will be no dead-load moment if the various parts of the structure are fabricated and erected to be cambered for the dead-load condition. Consequently, for dead load the stiffening girder takes only direct stress but, due to its parabolic arching, it carries a part of the dead load as stated by Eq. 2*b*. The girder, of course, is subjected to bending as well direct stresses due to live load, and the load taken in bending is expressed in Eq. 7.

Eqs. 45 for the independent values of the redundants that are assumed acting at the "elastic center" of the self-anchored suspension bridge are given by Mr. Eremin following the method suggested by Professor Krivoshein.[16] These or similar equations were first written by H. Müller-Breslau,[18] and also have been used by others. The lever arm d, or the vertical distance from the cable to the elastic center, is equal to $(f + a)(1 - e)$, in the notation of the paper, and also represents the moment at the center of the main span in the independent girder produced by the suspender forces for a unit value of H. It should be observed that in Eq. 46 the variable z has a different meaning from the z of the paper. The z of Eq. 46 is the vertical distance between the cable and the girder.

It may be of interest to elaborate somewhat on the type of self-anchored suspension bridge with unloaded side spans mentioned in the paper. Two bridges of this type have been built, both with the side-span girders hinged a short distance from the towers. The main-span girders were also hinged at the center for the dead-load condition. Neglecting the effect of side-span girder deflection, which is not neutralized as in the case of the main span by equal cable deflection, the formulas of the paper for the live-load condition will apply throughout when f_1 is placed equal to zero.

---

[18] "Die graphische Statik der Baukonstruktionen," by H. F. B. Müller-Breslau, Stuttgart, Alfred Kroner, 1920–1927.

In the self-anchored suspension bridge with unloaded side-span cables, the main-span girders will not be subjected to bending due to dead load when the stiffening girders are hinged at the towers. When the girders are continuous, however, the main-span girder must resist a constant negative dead-load moment that is the tower moment produced in the independent girder by a side-span loading equal to the difference between the side-span dead load and that portion of it taken by the side-span girder as a parabolic arch, provided the side-span girder is constructed to such a roadway camber. Both the side-span and main-span girders must be cambered vertically, for this side-span loading. If it is assumed that the entire side-span dead load is applied to the girders before the cables are connected to them, the girders then will deflect to a position with respect to their proper dead-load vertical position that will be below in the side span and above in the main span. The distortion required to make the cable-to-girder connection, due to the no-load shortness of the cable with respect to the girder, will be neutralized on application of the entire dead load in the main span. The parabolic arching of the side-span girders, where those girders do not follow a straight roadway grade, will relieve, in addition, the side-span girders of a part of the side-span dead load. This relief will have the effect of raising the side-span girders and lowering the main-span girders to their correct dead-load position.

The equation for dead-load bending at the center of the main span is:

$$M_w = T_D + \frac{w\,L^2}{8} - H_w\,a - H_w\,f = T_D \ldots\ldots\ldots\ldots (51)$$

in which T_D is the value of the bending moment at the tower, and therefore $H_w = \frac{w\,L^2}{8(f + a)}$, as for the bridge with loaded side spans. In the side span the equation for dead-load bending moment is:

$$M_{w1} = T_D\,\frac{x}{L_1} + \frac{w_1}{2}\,(L_1\,x - x^2) - H_w\,z_1 \ldots\ldots\ldots\ldots (52)$$

The second derivative of this expression gives the load taken by the side-span girder in bending:

$$w'_1 = w_1 - 8\,H_w\,\frac{a_1}{L^2_1} = w_1 - \frac{w\,L^2}{L^2_1} \times \frac{a_1}{(f + a)} \ldots\ldots\ldots (53)$$

The tower moment produced by this loading in the independent girder is the dead-load moment in the main span of the self-anchored suspension bridge with unloaded side-span cables.

ANALYSIS OF BUILDING FRAMES WITH SEMI-RIGID CONNECTIONS

By Bruce Johnston,[1] Assoc. M. Am. Soc. C. E., and
Edward H. Mount,[2] Esq.

With Discussion by Messrs. Maurice P. van Buren, Wayne W. Smith, Leonard P. Zick, Jr., and Conrad C. Wan, S. D. Lash, Dean F. Peterson, Jr., R. W. Stewart, Jaroslav J. Polivka, and Bruce Johnston and Edward H. Mount.

Synopsis

Methods applicable to the analysis of building frames with semi-rigid riveted or welded connections between the beams and columns are presented in this paper. The methods of analysis are too complex for ordinary design use, but the writers have presented simple design procedures, based on these methods of analysis, elsewhere (2) (3),[3] and have made them expeditious by the use of charts and diagrams. Such design methods effect permissible economy in the required beam sizes, made possible by considering the partial restraint afforded by standard or near standard connections, particularly riveted or welded connections of the top and seat angle type.

This paper also presents test results of a welded building frame that corroborate the methods of analysis. A study of the effect of neglecting the width of members in the analysis is presented. ("Member width" is used in this paper to indicate column width or beam depth, as the frame is viewed in elevation.) The essential features of the methods of analysis have been presented elsewhere (1) (13) (14), and it is the intention of the writers to modify them slightly so as to simplify the technique by conforming in every way to the usual slope-deflection and moment-distribution procedures.

Introduction

The design of the steel frames that form the skeleton of multiple-story steel buildings is usually based upon certain simplifying assumptions, chief of which are: (*a*) For the purpose of beam design the beam-column connections

---

Note.—Published in March, 1941, *Proceedings*.

[2] Formerly Am. Welding Soc. Research Fellow at Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

[3] Numerals in parentheses, thus: (2) (3), refer to corresponding numbers in the Bibliography; see Appendix.

are assumed to be pin connections, or simple supports; (*b*) columns are designed without attempting to evaluate the moments introduced by frame action; and (*c*) the beam-column connections are assumed to be rigid in calculating stresses due to lateral or wind loads.

These assumptions have afforded a means of rapid design calculation. Riveted building frames constructed on the basis of these design assumptions have proved to be safe and reliable, but there remains the possibility of achieving greater economy through the use of more nearly correct design assumptions. According to the British investigations (1), an average saving in the weight of beams of as much as 20% may be expected by taking advantage of the partial end restraint of riveted beam-column connections. Welded construction, with its inherent continuity, also makes similar saving in weight possible.

The basis for the application of more accurate design methods to frames with semi-rigid connections has already been laid in Great Britain (1) and in work of a parallel nature in the United States (2) (3) (4). The comparison of analytical and experimental results presented in this paper was made possible by the construction and test of a welded building frame with three bays and two stories. The beam-column connections used in this frame were of a semi-rigid type previously studied at the Fritz Engineering Laboratory (2) (5) in connection with research programs sponsored by the American Welding Society. Similar tests on riveted building frames have been made in Great Britain (1).

The slope-deflection and moment-distribution methods have as a common purpose the determination of the bending moments at the ends of the individual members of a statically indeterminate frame. Both methods in their usual form are based on the assumption that the deformations of the frames are caused entirely by bending of the members and that the relation between bending moment and distortion is given by the beam formula:

$$\frac{M}{E\,I} = \frac{d^2y}{dx^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The derivation of the beam theory and the assumptions on which it is based may be found in any text on the strength of materials.

In 1915 the slope-deflection method was applied in the United States (by Wilbur M. Wilson and George A. Maney, Members, Am. Soc. C. E.) to the analysis of wind stresses in tall buildings (6). A more complete treatment followed in 1918 (by Professor Wilson, with F. E. Richart and Camillo Weiss, Members, Am. Soc. C. E.) (7), and in 1931 a modification (8) was introduced by L. T. Evans, Assoc. M. Am. Soc. C. E., to take care of members with varying moments of inertia. The method of moment distribution was first presented in mimeographed form by Hardy Cross, M. Am. Soc. C. E., in 1926 (9) (10) (12). Innumerable variations and short cuts have been applied to the moment-distribution method and, although some of these have merit, the original method remains the outstanding development in recent times for rapid and effective analysis of continuous frames. The application of both the slope-deflection and moment-distribution methods to the analysis of frames with semi-rigid connections was made by John F. Baker, Assoc. M.

Am. Soc. C. E. (13). The width of the members and the semi-rigid nature of the connections are both taken into account, as it is found that the neglect of member width gives rise to considerable error, particularly in the case of analyses of frames with semi-rigid connections.

ANALYSIS OF FRAMES WITH SEMI-RIGID JOINTS

It will be assumed that the reader is already familiar with the usual application of the slope-deflection and moment-distribution methods, for which references are readily available (12) (15) (16) (17). The methods herein presented are identical in mode of application to the usual simple form, with the exception that special coefficients must be used in the slope-deflection equations and for the carry-over and distribution factors in the moment-distribution method. The following method is identical with that previously presented by Professor Baker (13) (14) when the width of member is neglected. When the width of member is considered, the following method differs in two respects from that of Professor Baker: (*a*) The interior of the joint between connections is assumed infinitely rigid, whereas Professor Baker assumes it to have the same stiffness as the beam; and (*b*) hypothetical moments are computed at the joint centers by the usual slope-deflection and moment-distribution procedures, whereas in Professor Baker's method separate expressions are given for the moment and shear at the connection, or column face, and are dealt with separately.

The following assumptions apply both to the slope-deflection and to the moment-distribution relations as herein presented: (*a*) Members are of uniform cross section between their end connections; (*b*) the semi-rigid connection at the end of a member behaves elastically as defined by the connection constant γ; and (*c*) the interior of the joint between connections is assumed to be infinitely rigid, although free to rotate as a rigid body.

The notation used is shown subsequently in Figs. 5 and 6. The hypothetical moments and shears at the joint centers, when width of column is considered, are designated by the bar above the letter M or V, thus; $\bar{M}$ and $\bar{V}$.

The "Semi-Rigid" Connection.—The semi-rigid connection may be thought of as a locally weakened section between the end of the beam and the face of the column to which the connection is made. The effect on analysis is the inverse of the effect produced by end haunches or added cover plates. The typical test behavior of a riveted or welded connection of this type is shown in Fig. 1, which presents the plot of the relationship between moment transmitted through the connection and the angle change between the joint center and the end of the beam. In the design range the relationship is assumed linear and the inverse slope is termed the connection constant, γ, thus:

$$\gamma = \frac{\phi}{M} = \frac{\text{Angle change}}{\text{Moment}} \qquad \text{(2)}$$

The connection constant γ may be defined as "angle change for unit moment" and may be determined experimentally by testing typical joints. The vertical line through the origin in Fig. 1 would indicate the behavior of a perfectly fixed connection with $\gamma = 0$, and the horizontal line would represent the behavior of a frictionless pin connection, in which case $\gamma = \infty$. Fig. 2(*a*)

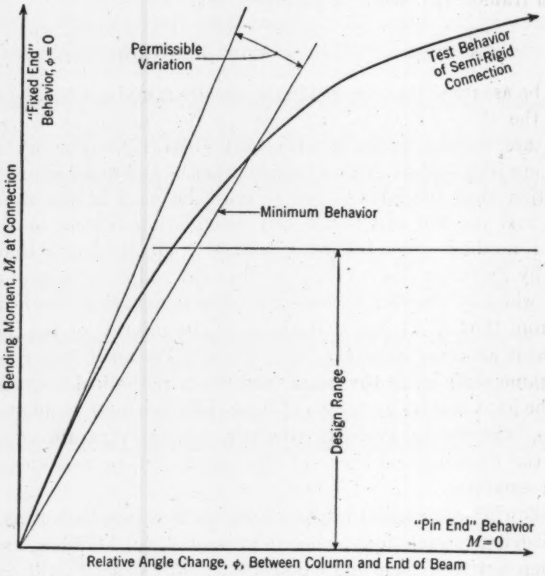

FIG. 1.—TYPICAL M-ϕ RELATION IN THE TEST OF A WELDED OR RIVETED BEAM-COLUMN CONNECTION

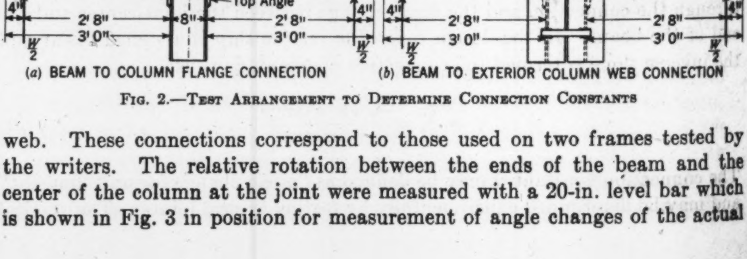
shows the test setup for determining the connection constant at an interior joint of a frame with beam-to-column-flange connections, and Fig. 2(*b*) shows a similar setup to test the connection between a beam and an exterior column



(*a*) BEAM TO COLUMN FLANGE CONNECTION (*b*) BEAM TO EXTERIOR COLUMN WEB CONNECTION

FIG. 2.—TEST ARRANGEMENT TO DETERMINE CONNECTION CONSTANTS

web. These connections correspond to those used on two frames tested by the writers. The relative rotation between the ends of the beam and the center of the column at the joint were measured with a 20-in. level bar which is shown in Fig. 3 in position for measurement of angle changes of the actual test frame. Fig. 4 is a graph within the test-design range of measured angle change plotted against moment in typical joint tests corresponding to the actual test frame.

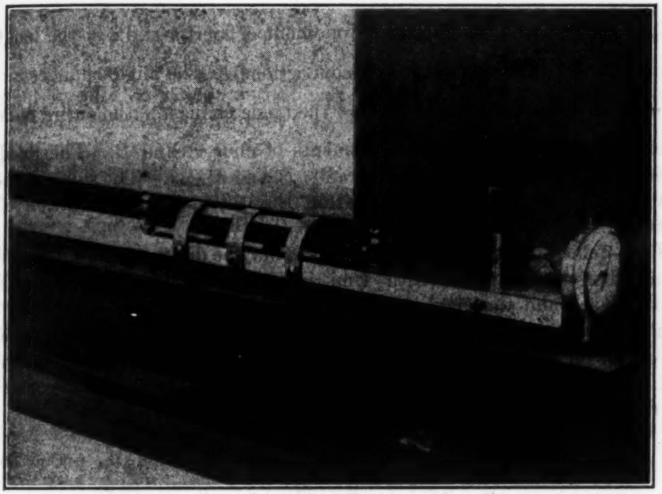


FIG. 3.—LEVEL BAR USED TO MEASURE ROTATIONS

The Slope-Deflection Equations.—For any individual member of a frame, the relation between its end moments, the angle changes at each end, and the angle change of the member as a whole may be expressed by a pair of slope-deflection equations. For the usually assumed case of uniform beam cross

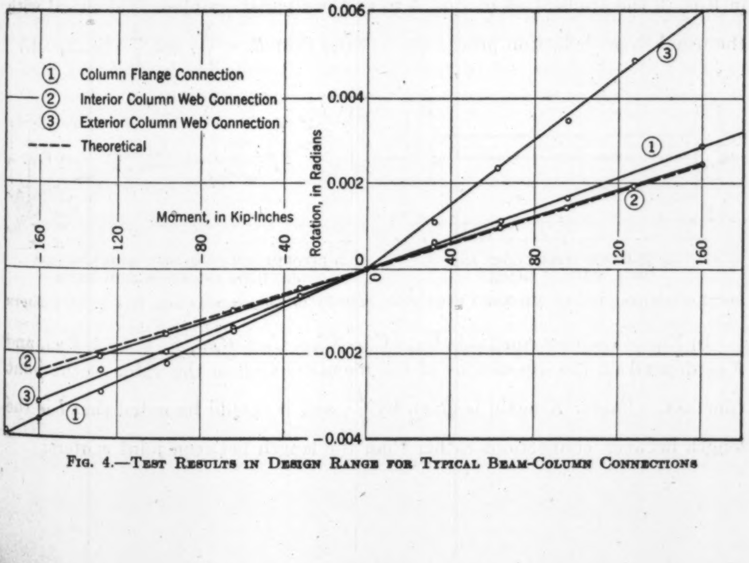

FIG. 4.—TEST RESULTS IN DESIGN RANGE FOR TYPICAL BEAM-COLUMN CONNECTIONS

section, and with rigid end connections, these equations are written:

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R) - M_{RAB} \qquad (3a)$$

and

$$M_{BA} = 2\,E\,K\,(2\,\theta_B + \theta_A - 3\,R) + M_{RBA} \qquad (3b)$$

In Eqs. 3, $K = \frac{I}{l}$, in which I = the moment of inertia and l = the length of the member (distance between joint connections). The angle changes at ends A and B are θ_A and θ_B; and $R = \frac{\Delta}{l}$ = the angle change of the entire member, Δ being the relative lateral displacements of ends A and B. The fixed-end moments for the lateral loads alone are M_{RAB} and M_{RBA}. The slope-deflection equations may be derived directly from Eq. 1 or by an application of the moment-area principles.

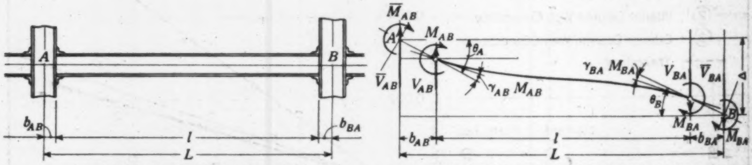
Slope-deflection equations such as Eqs. 3 may be derived by similar methods for members which frame with semi-rigid connections. Fig. 5 shows the notation used and the geometry of the general deflected curve of any such member. Note especially Fig. 5(*b*), which shows the hypothetical moments at the center of the joint. The slope-deflection equations corresponding to Eqs. 3 for the hypothetical moments $\bar{M}_{AB}$ and $\bar{M}_{BA}$ at the joint centers for any member $A\,B$, as shown in Fig. 5, may be written:

$$\bar{M}_{AB} = \frac{1}{1 + 2\,\alpha + 2\,\beta + 3\,\alpha\,\beta}\,[2\,E\,K(C_{AA}\,\theta_A + C_{AB}\,\theta_B - C_{AC}\,R) - F_{AA}\,M_{RAB} - F_{AB}\,M_{RBA}] - V_{AB}'\,b_{AB} \qquad (4a)$$

and

$$\bar{M}_{BA} = \frac{1}{1 + 2\,\alpha + 2\,\beta + 3\,\alpha\,\beta}\,[2\,E\,K(C_{BB}\,\theta_B + C_{BA}\,\theta_A - C_{BC}\,R) + F_{BB}\,M_{RBA} + F_{BA}\,M_{RAB}] + V_{BA}'\,b_{BA} \qquad (4b)$$

Except for the fact that new coefficients replace the even integer coefficients in Eqs. 3, the application of Eqs. 4 to any particular problem is identical with the usual slope-deflection procedure. (Note that $R = \frac{\Delta}{l}$, not $\frac{\Delta}{L}$, in Eqs. 4.)



(*a*) SEMI-RIGID CONNECTIONS AND FINITE WIDTH OF MEMBER

(*b*) DEFORMATION OF MEMBER WITH SEMI-RIGID CONNECTIONS AND FINITE JOINT WIDTH

FIG. 5.—DEFORMATION OF MEMBER CONSIDERING SEMI-RIGID CONNECTIONS AND FINITE JOINT WIDTH

In Eqs. 4 the new constants C_{AA}, C_{AB}, C_{AC}, C_{BB}, C_{BA}, F_{AA}, F_{AB}, F_{BA}, and F_{BB} depend on the dimensions of the members and on the value of the joint constant. Factor K again is given by $\frac{I}{l}$, and it should be noted that l is the length between connections rather than the length between joint centers.

The connection constants γ_A and γ_B for the connections at the two ends of the beam are introduced into new constants α and β by the relations (1):

$$\alpha = 2\,E\,K\,\gamma_A \tag{5a}$$

and

$$\beta = 2\,E\,K\,\gamma_B \tag{5b}$$

The fixed-end moments for a member with fixed, rigidly connected, ends of span length l are M_{RAB} and M_{RBA}; and V_{AB}' and V_{BA}' are the shears or reactions at the ends of a member with freely supported ends and span length l.

The constants C_{AA}, C_{AB}, C_{AC}, F_{AA}, and F_{AB} in Eq. 4*a* are given in Table 1 for four different cases. All four cases are for unsymmetrical conditions, the first and the third considering semi-rigid connections, and the second and fourth considering rigid connections. In cases I and II, a finite width of member is considered; and, in cases III and IV, width is ignored. The values in case IV are those commonly assumed—that is, frames with rigid joints and with width of member neglected. In Eq. 4*b* the constants C_{BB}, C_{BA}, C_{BC}, F_{BB}, and F_{BA} for $\bar{M}_{BA}$ are obtained from C_{AA}, C_{AB}, C_{AC}, F_{AA}, and F_{AB}, respectively, by interchanging α and β and the subscripts A and B. It is noted that C_{BA} is equal to C_{AB}.

Eqs. 4 with the preceding coefficients are for moments at the joint centers and therefore are used with exactly the same equilibrium conditions as in the simpler form (2); namely,

For joint equilibrium,

$$\Sigma \bar{M} = 0 \tag{6a}$$

and, for story equilibrium,

$$\Sigma \bar{M} + V\,h = 0 \tag{6b}$$

In Eq. 6*b*, h is the story height between neutral axes of two beams.

With Eqs. 4 it is now possible to determine the hypothetical end moments $\bar{M}_{AB}$ and $\bar{M}_{BA}$ at the joint centers. Moments and shears are assumed as positive when they act on the ends of the beam with a clockwise sense, or act on the joint with a counterclockwise sense. The hypothetical shears in the joint are constant and equal to the actual shear at the connection. The shears $\bar{V}_{AB}$ and $\bar{V}_{BA}$ may be calculated from the moments $\bar{M}_{AB}$ and $\bar{M}_{BA}$ by the following:

$$V_{AB} = \bar{V}_{AB} = -\left(\frac{\bar{M}_{AB} + \bar{M}_{BA}}{L}\right) + \bar{V}_{AB}' \tag{7a}$$

and

$$V_{BA} = \bar{V}_{BA} = -\left(\frac{\bar{M}_{AB} + \bar{M}_{BA}}{L}\right) - \bar{V}_{BA}' \tag{7b}$$

in which $\bar{V}_{AB}'$ and $\bar{V}_{BA}'$ are the end shears in a member having span length L with simply or freely supported ends. The moments at the connections, M_{AB} and M_{BA}, may now be calculated from the following:

$$M_{AB} = \bar{M}_{AB} + \bar{V}_{AB}\,b_{AB} \tag{8a}$$

and

$$M_{BA} = \bar{M}_{BA} + \bar{V}_{BA}\,b_{BA} \tag{8b}$$

TABLE 1.—SLOPE-DEFLECTION AND MOMENT-DISTRIBUTION CONSTANTS—NONSYMMETRICAL CASES

Constant	Case I—Nonsymmetrical, semi-rigid connections, finite width of members	Case II—Nonsymmetrical, rigid connections, finite widths	Case III—Nonsymmetrical, semi-rigid connections, zero width	Case IV—Rigid connections, 0 width
	(a) SLOPE DEFLECTION			
C_{AA}	$2 + 3\beta + 6(1+\beta)\frac{b_{AB}}{l} + 3(2+\alpha+\beta)\frac{b_{AB}^2}{l^2}$	$2 + \frac{6\,b_{AB}}{l} + \frac{6\,b_{AB}^2}{l^2}$	$2 + 3\beta$	2
$C_{AB} = C_{BA}$	$1 + 3(1+\alpha)\frac{b_{AB}}{l} + 3(1+\beta)\frac{b_{BA}}{l} + 3(2+\alpha+\beta)\frac{b_{AB}\,b_{BA}}{l^2}$	$1 + \frac{3\,b_{AB}}{l} + \frac{3\,b_{BA}}{l} + \frac{6\,b_{AB}\,b_{BA}}{l^2}$	1	1
C_{BB}	$2 + 3\alpha + 6(1+\alpha)\frac{b_{BA}}{l} + 3(2+\alpha+\beta)\frac{b_{BA}^2}{l^2}$	$2 + \frac{6\,b_{BA}}{l} + \frac{6\,b_{BA}^2}{l^2}$	$2 + 3\alpha$	2
C_{AC}	$3(1+\beta) + 3(2+\alpha+\beta)\frac{b_{AB}}{l}$	$3 + \frac{6\,b_{AB}}{l}$	$3(1+\beta)$	3
C_{BC}	$3(1+\alpha) + 3(2+\alpha+\beta)\frac{b_{BA}}{l}$	$3 + \frac{6\,b_{BA}}{l}$	$3(1+\alpha)$	3
F_{AA}	$1 + 2\beta + (1-\alpha+2\beta)\frac{b_{AB}}{l}$	$1 + \frac{b_{AB}}{l}$	$1 + 2\beta$	1
F_{AB}	$\beta + (\beta - 2\alpha - 1)\frac{b_{AB}}{l}$	$-\frac{b_{AB}}{l}$	β	0
F_{BB}	$1 + 2\alpha + (1-\beta+2\alpha)\frac{b_{BA}}{l}$	$1 + \frac{b_{BA}}{l}$	$1 + 2\alpha$	1

$\bar{S}_{MAB}$ end rotation stiffness	$\frac{2\,E\,K\left[2 + 3\beta + 6(1+\beta)\frac{b_{AB}}{l} + 3(2+\alpha+\beta)\frac{b_{AB}^2}{l^2}\right]}{1+2\alpha+2\beta+3\alpha\beta}$	$2\,E\,K\left(2 + \frac{6\,b_{AB}}{l} + \frac{6\,b_{AB}^2}{l^2}\right)$	$\frac{2\,E\,K\,(2+3\beta)}{1+2\alpha+2\beta+3\alpha\beta}$	$4\,E\,K$
$\bar{S}_{VAB}$ sidesway stiffness	$\frac{6\,E\,K}{l^2}\left(\frac{2+\alpha+\beta}{1+2\alpha+2\beta+3\alpha\beta}\right)$	$\frac{12\,E\,K}{l^3}$	$\frac{6\,E\,K}{l^2}\left(\frac{2+\alpha+\beta}{1+2\alpha+2\beta+3\alpha\beta}\right)$	$\frac{12\,E\,K}{l^2}$
$\bar{M}_{VAB}$ sidesway end moment at A	$-\frac{6\,E\,K}{l}\left[\frac{1+\beta+\frac{b_{AB}}{l}(2+\alpha+\beta)}{1+2\alpha+2\beta+3\alpha\beta}\right]$	$-\frac{6\,E\,K}{l}\left(1+\frac{2\,b_{AB}}{l}\right)$	$-\frac{6\,E\,K}{l}\left(\frac{1+\beta}{1+2\alpha+2\beta+3\alpha\beta}\right)$	$-\frac{6\,E\,K}{l}$

The slope-deflection equations are simplified when symmetrical conditions of loading and structure exist with respect to any particular member. In such a case $\alpha = \beta$. Furthermore, $b_{AB} = b_{BA} = b$; $M_{RAB} = M_{RBA} = M_R$; $\bar{V}_{AB}' = \bar{V}_{BA}' = V_{AB}' = V_{BA}' = V'$; and the slope-deflection equations corresponding to case I of Table 1 may be reduced to:

$$\bar{M}_{AB} = \frac{2\,E\,K}{1 + 3\,\alpha}\left[\left(\frac{2 + 3\,\alpha}{1 + \alpha} + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_A + \left(\frac{1}{1 + \alpha} + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_B - \left(3 + \frac{6\,b}{l}\right)R\right] - \left(\frac{M_R}{1 + \alpha} + V'\,b\right) \qquad (9a)$$

and

$$\bar{M}_{BA} = \frac{2\,E\,K}{1 + 3\,\alpha}\left[\left(\frac{2 + 3\,\alpha}{1 + \alpha} + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_B + \left(\frac{1}{1 + \alpha} + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_A - \left(3 + \frac{6\,b}{l}\right)R\right] + \left(\frac{M_R}{1 + \alpha} + V'\,b\right) \qquad (9b)$$

For case II of Table 1, considering the semi-rigidity of the joints but neglecting the width of the members, the equations for symmetrical conditions may be reduced to a simple form by letting $b = 0$ in Eqs. 9; thus:

$$\bar{M}_{AB} = M_{AB} = \frac{2\,E\,K}{1 + 3\,\alpha}\left[\left(\frac{2 + 3\,\alpha}{1 + \alpha}\right)\theta_A + \left(\frac{1}{1 + \alpha}\right)\theta_B - 3\,R\right] - \frac{M_R}{1 + \alpha} \qquad (10a)$$

and

$$\bar{M}_{BA} = M_{BA} = \frac{2\,E\,K}{1 + 3\,\alpha}\left[\left(\frac{2 + 3\,\alpha}{1 + \alpha}\right)\theta_B + \left(\frac{1}{1 + \alpha}\right)\theta_A - 3\,R\right] + \frac{M_R}{1 + \alpha} \qquad (10b)$$

A similar simplification may be made for case III of Table 1 by letting $\alpha = 0$ in Eqs. 9, in which case the following equations result:

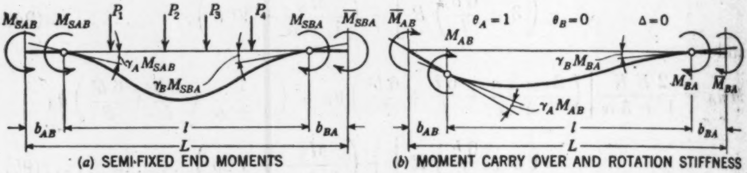
$$\bar{M}_{AB} = 2\,E\,K\left[\left(2 + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_A + \left(1 + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_B - \left(3 + \frac{6\,b}{l}\right)R\right] - (M_R + V_b') \qquad (11a)$$

and

$$\bar{M}_{BA} = 2\,E\,K\left[\left(2 + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_B + \left(1 + \frac{6\,b}{l} + \frac{6\,b^2}{l^2}\right)\theta_A - \left(3 + \frac{6\,b}{l}\right)R\right] + (M_R + V_b') \qquad (11b)$$

Moment Distribution Applied to Frames with Semi-Rigid Connections.—The moment-distribution method serves identically the same purpose as the slope-deflection method; that is, the moments at the ends of the individual members of a frame or continuous beam are determined. It will be assumed, as in the case of the slope-deflection method, that the reader is familiar with the usual moment distribution procedure. The procedure as applied to frames with semi-rigid connections is identical with the usual method, although there are differences in the numerical value of the carry-over, stiffness, and other factors.

The factors used in the moment-distribution procedure may be derived from the slope-deflection equations or by use of the column analogy (11), as will be described herein. Fig. 6 shows the deformation conditions for determining semi-rigid end moments and the carry-over factor for moment distribution. Table 1 gives the "semi-rigid" end moments, "carry-over" factor, rotation-stiffness factors, sidesway-stiffness factors, and sidesway end moments for the nonsymmetrical cases I, II, III, and IV. Table 2 presents the same factors for the symmetrical cases I, II, and III.



(a) SEMI-FIXED END MOMENTS (b) MOMENT CARRY OVER AND ROTATION STIFFNESS

FIG. 6.—DEFORMATION CONDITIONS USED IN MOMENT DISTRIBUTION FOR MEMBERS WITH SEMI-RIGID CONNECTIONS AND FINITE JOINT WIDTH

TABLE 2.—MOMENT DISTRIBUTION FOR SYMMETRICAL CASES
$\alpha = \beta$, $b_{AB} = b_{BA} = b$, AND $M_{RA} = M_{RB} = M_R$

Constant	Symmetrical case I, semi-rigid connections, finite width of members	Symmetrical case II, rigid connections, finite member width	Symmetrical case III, semi-rigid connections, zero member width
$\bar{M}_{SAB}$ semi-fixed-end moment at joint center	$\frac{M_R}{1+\alpha} + V' b$	$M_R + V' b$	$\frac{M_R}{1+\alpha}$
$\bar{r}_{AB}$ carry-over factor between joint centers	$\frac{1+6(1+\alpha)\frac{b}{l}+6(1+\alpha)\frac{b^2}{l^2}}{2+3\alpha+6(1+\alpha)\frac{b}{l}+6(1+\alpha)\frac{b^2}{l^2}}$	$\frac{1+\frac{6b}{l}+\frac{6b^2}{l^2}}{2+\frac{6b}{l}+\frac{6b^2}{l^2}}$	$\frac{1}{2+3\alpha}$
$\bar{S}_{MAB}$ end rotation stiffness	$\frac{2EK}{1+3\alpha}\left(\frac{2+3\alpha}{1+\alpha}+\frac{6b}{l}+\frac{6b^2}{l^2}\right)$	$2EK\left(2+\frac{6b}{l}+\frac{6b^2}{l^2}\right)$	$2EK\left(\frac{2+3\alpha}{1+4\alpha+3\alpha^2}\right)$
$\bar{S}_{VAB}$ sidesway stiffness	$\frac{12EK}{l^2(1+3\alpha)}$	$\frac{12EK}{l^2}$	$\frac{12EK}{l^2(1+3\alpha)}$
$\bar{M}_{VAB}$ sidesway end moment at A	$-\frac{6EK}{l}\left(\frac{1+\frac{2b}{l}}{1+3\alpha}\right)$	$-\frac{6EK}{l}\left(1+\frac{2b}{l}\right)$	$-\frac{6EK}{l(1+3\alpha)}$

All of the moment-distribution factors relate to hypothetical moments at the centers of the joints, and the general procedure is therefore identical with that used in the simple case. After the hypothetical moments at the joint centers are obtained, the moments and shears at the connections result as before from Eqs. 7 and 8.

In applying the moment-distribution method to frame problems, sidesway may be induced either by lateral loads or by unsymmetrical conditions of loading or frame arrangement. The simplest form of sidesway problem is one involving only lateral loads applied to a one-story frame. The lateral load is distributed to the columns in proportion to their "sidesway stiffness" $\bar{S}_V$, and semi-fixed or fixed-end moments are distributed to the ends of each column in proportion to the $\bar{M}_V$ moments for unit sidesway. The next step is the usual moment distribution, but at the conclusion the summation of column shears will not account for the total lateral force. All of the end moments are then multiplied by a constant ratio sufficient to bring the shears into equilibrium with the external lateral force. If the structure is more than one story in height, the procedure is progressively more complicated. Shears are distributed in any one story in proportion to their lateral or sidesway stiffness; but in special cases in which two-story sections adjoin open auditoriums or halls, the combined rigidities of the two stories of columns "in series" must be determined. The stiffness of a two-story group of columns "in series" is given by:

$$\bar{S}_{VABC} = \frac{\bar{S}_{VAB}\,\bar{S}_{VBC}}{\bar{S}_{VAB} + \bar{S}_{VBC}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

in which $\bar{S}_{VABC}$ = sidesway stiffness of two columns or groups of columns "in series." The combined rigidity of three tiers of columns "in series" is given by:

$$\bar{S}_{VABCD} = \frac{\bar{S}_{VAB}\,\bar{S}_{VBC}\,\bar{S}_{VCD}}{\bar{S}_{VAB}\,\bar{S}_{VBC} + \bar{S}_{VBC}\,\bar{S}_{VCD} + \bar{S}_{VCD}\,\bar{S}_{VAB}} \quad \ldots\ldots (12b)$$

The analysis of two-story and three-story problems of the foregoing type is taken up in texts (12) (16) (17) and the procedure for frames with semi-rigid joints follows exactly the same course. In applying these analytical methods to the development of design methods for multi-storied buildings, under the action of vertical loads alone, it is reasonable to neglect the effect of sidesway.

Certain short cuts for special conditions may be used, provided that their use in simpler forms of moment distribution is already familiar. For example, if the end B of member $A\,B$ is pin-connected, or freely supported, β becomes equal to ∞. The "semi-fixed" end moment at A then becomes:

$$\bar{M}_{SAB} = \left(\frac{2 + \frac{2\,b_{AB}}{l}}{2 + 3\,\alpha}\right) M_{RAB} + V_A'\,b_{AB} \quad \ldots\ldots\ldots\ldots (13)$$

In Eq. 13 M_{RAB} is the fixed-end moment at A due to lateral loads in a beam freely supported at B. The rotation stiffness, or distribution factor, for end A of member $A\,B$ with B freely supported is:

$$\bar{S}_{MAB} = \frac{2\,E\,K}{2 + 3\,\alpha}\left(3 + \frac{6\,b_{AB}}{l} + \frac{3\,b_{AB}{}^2}{l^2}\right) \quad \ldots\ldots\ldots\ldots (14a)$$

The sidesway stiffness factor for the same case, with one end freely supported, is as follows:

$$\bar{S}_{VAB} = \frac{6\,E\,K}{l^2\,(2 + 3\,\alpha)} \quad \text{(14b)}$$

Cases II and III in Table 2 may be obtained from Eqs. 13, 14*a*, and 14*b* by letting α and b_{AB}, respectively, be equal to zero.

Another type of special case occurs when the entire frame and loading upon it are symmetrical. If the center line of the frame is on line with a column, there will be no rotation of the column joints and the center line of the center column may be assumed equivalent to a fixed wall. If there are an odd number of panels, the center line of the frame will cut through the center of the beams in the center bay. The rotation of the two ends of each beam in the center panel will be equal in magnitude and opposite in sign. From this condition it follows that the modified moment stiffness or "distribution factor" may be taken as:

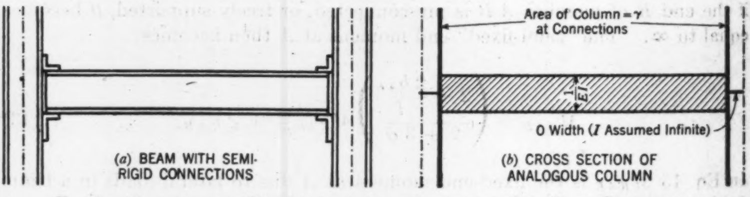
$$\bar{S}_{MAB} = \frac{2\,E\,K}{1 + \alpha} \quad \text{(14c)}$$

for the ends of beams in the center panel. No carry-over is used in the center panel when the modified stiffness factor is used.

Application of the Column Analogy to Members with Semi-Rigid Connections.—It will be assumed that the reader is familiar with the application of the column analogy, originally developed by Professor Cross (11), to the determination of moment-distribution factors for beams with variable moments of inertia. The width of the "analogous column" is equal to $\frac{1}{E\,I}$, and the area of any elemental length ds of the analogous column is therefore equal to $\frac{ds}{E\,I}$. From the fundamental relations of the bent beam,

$$\frac{d\phi}{M} = \frac{ds}{E\,I} \quad \text{(15)}$$

in which $d\phi$ = the angle change in any elemental length of beam. At the



Area of Column = γ at Connections
$\frac{1}{EI}$
0 Width (*I* Assumed Infinite)

(*a*) BEAM WITH SEMI-RIGID CONNECTIONS

(*b*) CROSS SECTION OF ANALOGOUS COLUMN

FIG. 7.—APPLICATION OF COLUMN ANALOGY TO BEAMS WITH SEMI-RIGID CONNECTIONS

particular location of the semi-rigid joint, from the definition of the "connection constant,"

$$\gamma = \frac{d\phi}{M} = \frac{ds}{E\,I} \quad \text{(16)}$$

Hence, the localized area of the analogous column at the semi-rigid connection is equal to the connection constant γ. Professor Cross (11) has shown that the area of the analogous column at a pin connection is infinite, and in the region of a completely rigid zone it is equal to zero. The semi-rigid connection obviously is a case somewhere between these two extremes, and the column analogy may readily be used to obtain the moment-distribution factors for a member so connected. Fig. 7 illustrates a cross section through the analogous column of a member with semi-rigid end connections.

ANALYSIS BY SLOPE-DEFLECTION METHOD

An illustrative example will be presented in detail to demonstrate the application of both the slope-deflection and moment-distribution methods to the analysis of a frame with semi-rigid joints, taking into account the width of the members.

The frame shown in Fig. 8 corresponds to one of the frames actually tested (see Fig. 9), and the connection constant used in the analysis was obtained experimentally from tests of a sample joint. All of the connections were identically alike, and each beam, therefore, was individually symmetrical. The results of the connection test gave an experimental value of $\gamma = 0.01775 \times 10^{-3}$ in inch-kip units. The stiffness of the frame members was measured by bending tests preliminary to fabrication of the frame, and the quantity $E\,I$ was thus found to be $3{,}550 \times 10^3$ and $3{,}321 \times 10^3$ for the beams and columns, respectively, in inch-kip units. The net length l of the beams between connections was 168 in. − 8 in. = 160 in. The columns are continuous, and the beam connections were of the welded seat and top angle type. An approximate correction for column length may be shown to be one third of the beam depth at each end that frames with a beam (see heading "Effect of Width of Member Upon Analysis"). Hence, for the second-story columns, $l = 120 - 6.67 = 113.33$ and, for the first-story columns, $l = 120 - 3.33 = 116.67$. This correction could well be omitted with but little error.

The constant α for the beams was

$$\alpha = \beta = \frac{2\,E\,I\,\gamma}{l} = \frac{2 \times 3{,}550 \times 10^3 \times 0.01775 \times 10^{-3}}{160} = 0.7877.$$

The fixed-end moment for the loading shown is 221.0 in-kips.

Because of the individual symmetry of the beams, the slope-deflection equations in the form of Eqs. 9 were applicable. The typical equation for any beam is written by substituting the values of α, $E\,K$, b, l, etc., in Eqs. 9, which for any loaded beam results in the following:

$$\bar{M}_{AB} = \frac{2 \times 3{,}550}{160(1 + 3 \times 0.7877)}\left\{\left[\left(\frac{2 + 3 \times 0.7877}{1 + 0.7877}\right) + \frac{6 \times 4}{160} + \frac{6 \times 4^2}{160^2}\right]\theta_A\right.$$

$$\left. + \cdots + \left[\left(\frac{1}{1 + 0.7877}\right) + \frac{6 \times 4}{160} + \frac{6 \times 4^2}{160^2}\right]\theta_B\right\} - \left(\frac{221.0}{1.7877} + 6.5 \times 4\right) \quad \text{..(17)}$$

The right-hand side of this and the following equations has been divided by 1,000 to give more convenient values of θ. The moment $\bar{M}_{AB} = 34.233\,\theta_A$

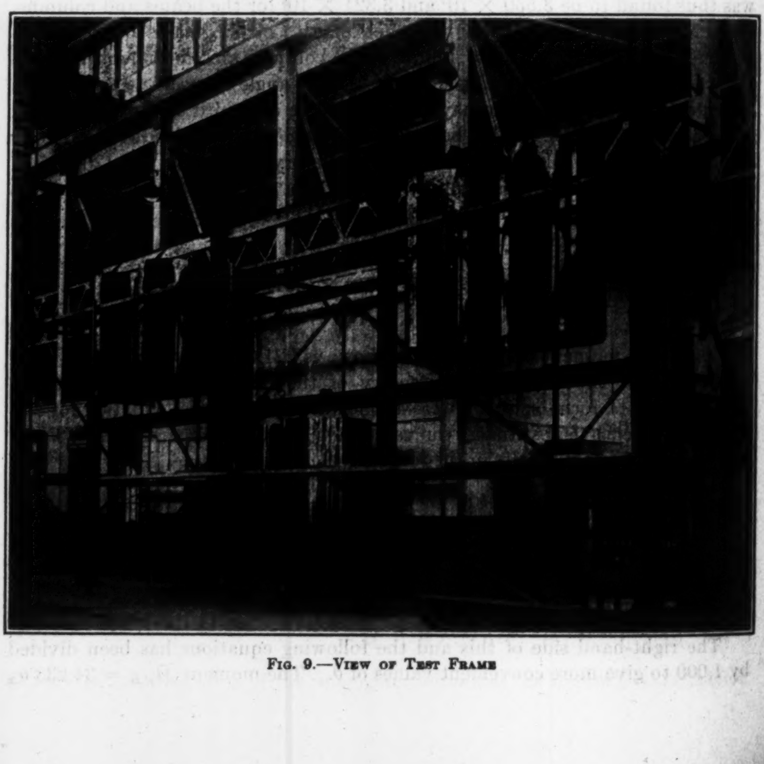

FIG. 9.—VIEW OF TEST FRAME

$+ 9.411\,\theta_B - 149.62$; and similarly:

$$\bar{M}_{BA} = 34.233\,\theta_B + 9.411\,\theta_A + 149.62 \qquad (18)$$

Equations of this type are written for all of the beams in a symmetrical half of the frame, as follows:

$$\left.\begin{aligned}
\bar{M}_{12} &= 34.233\,\theta_1 + 9.411\,\theta_2 \\
\bar{M}_{21} &= 34.233\,\theta_2 + 9.411\,\theta_1 \\
\bar{M}_{27} &= 34.233\,\theta_2 + 9.411\,\theta_7 - 149.62 \qquad (-\theta_2 = +\theta_1) \\
&= 24.822\,\theta_2 - 149.62 \\
\bar{M}_{34} &= 34.233\,\theta_3 + 9.411\,\theta_4 - 149.62 \\
\bar{M}_{43} &= 34.233\,\theta_4 + 9.411\,\theta_3 + 149.62 \\
\text{and} \quad \bar{M}_{48} &= 24.822\,\theta_4 \qquad (-\theta_4 = +\theta_8)
\end{aligned}\right\} \quad (19)$$

Similar equations for the column moments are written by making the proper substitutions in slope-deflection Eqs. 11, as follows:

$$\left.\begin{aligned}
\bar{M}_{13} &= 127.865\,\theta_1 + 69.257\,\theta_3 \\
\bar{M}_{24} &= 127.865\,\theta_2 + 69.257\,\theta_4 \\
\bar{M}_{31} &= 127.865\,\theta_3 + 69.257\,\theta_1 \\
\bar{M}_{42} &= 127.865\,\theta_4 + 69.257\,\theta_2 \\
\bar{M}_{35} &= 123.910\,\theta_3 \qquad (\theta_5 = 0) \\
\bar{M}_{46} &= 123.910\,\theta_4 \qquad (\theta_6 = 0) \\
\bar{M}_{53} &= 61.810\,\theta_3 \qquad (\theta_5 = 0) \\
\text{and} \quad \bar{M}_{64} &= 61.810\,\theta_4 \qquad (\theta_6 = 0)
\end{aligned}\right\} \quad (20)$$

The sidesway is obviously zero because of symmetry, and the only unknowns are the four angle changes θ_1, θ_2, θ_3, and θ_4. The necessary and sufficient conditions for the solution are obtained by applying the joint equilibrium equation $\Sigma M = 0$ to the four joints 1, 2, 3, and 4:

$$\left.\begin{aligned}
\bar{M}_{12} + \bar{M}_{13} &= 0 \\
\bar{M}_{21} + \bar{M}_{24} + \bar{M}_{27} &= 0 \\
\bar{M}_{31} + \bar{M}_{34} + \bar{M}_{35} &= 0 \\
\text{and} \quad \bar{M}_{43} + \bar{M}_{42} + \bar{M}_{48} + \bar{M}_{46} &= 0
\end{aligned}\right\} \quad (21)$$

Rewriting these equations in terms of the unknown θ's:

$$\left.\begin{aligned}
+ 162.098\,\theta_1 + 9.411\,\theta_2 + 69.257\,\theta_3 &= 0 \\
9.411\,\theta_1 + 186.920\,\theta_2 + 69.257\,\theta_4 &= + 149.620 \\
+ 69.257\,\theta_1 + 286.008\,\theta_3 + 9.411\,\theta_4 &= + 149.620 \\
+ 69.257\,\theta_2 + 9.411\,\theta_3 + 310.830\,\theta_4 &= - 149.620
\end{aligned}\right\} \quad (22)$$

The solution of these four simultaneous equations may be made by systematic elimination of unknowns (15) (16) or by a method of successive approximations (15). The following solution was obtained by the first method: $\theta_1 = -0.33174$;

$\theta_2 = +1.09276$; $\theta_3 = +0.62795$; and $\theta_4 = -0.74385$. These values of θ are 1,000 times the actual values but will give the correct moments when substituted in the moment equations which previously had been divided by 1,000. The actual moments at the connections may be found from the hypothetical joint center moments by computing the shears with Eqs. 7 and the connection moments with Eqs. 8. An alternate method would be to construct, graphically, the simple beam moment diagram for the full lengths L upon the joint moment base line. The connection moments then could be scaled off as the ordinate to the moment diagram at the face of the connecting member. Table 3 gives the results by the analytical method.

ANALYSIS BY MOMENT DISTRIBUTION

The factors required in the moment-distribution procedure have been presented in Tables 1 and 2. Some of the necessary computations in the following have already been made under the heading "Analysis by Slope-Deflection Method":

Semi-Fixed End Moment at Joint Center.—

$$\bar{M}_{SAB} = \frac{221.0}{1.7877} + 6.5 \times 4 = 149.62 \text{ in-kips.}$$

Carry-Over Factors Between Joint Centers.—

Beams (Both Directions).—

$$\bar{r}_{ab} = \bar{r}_{ba} = \frac{1 + 6\,(1.7877)\,\frac{4}{160} + 6\,(1.7877)\,\frac{4^2}{160^2}}{2 + 3\,(0.7877) + 6\,(1.7877)\,\frac{4}{160} + 6\,(1.7877)\,\frac{4^2}{160^2}} = 0.275.$$

Second-Story Columns (Both Directions).—

$$r = \frac{1 + 6\left(\frac{3.33}{113.33}\right) + 6\left(\frac{3.33^2}{113.33^2}\right)}{2 + 6\left(\frac{3.33}{113.33}\right) + 6\left(\frac{3.33^2}{113.33^2}\right)} = 0.542.$$

First-Story Columns (Top to Bottom) (See Table 1).—

$$r = \frac{1 + 3\left(\frac{3.33}{116.67}\right)}{2 + 6\left(\frac{3.33}{116.67}\right) + 6\left(\frac{3.33}{116.67}\right)^2} = 0.499.$$

End Rotation Stiffness at Joint Centers.—

Beams (End Bay).—

$$\bar{S}_M = \frac{2\ (3{,}550) \times 10^6}{160\ [1 + 3\ (0.7877)]} \left[\frac{2 + 3\ (0.7877)}{1.7877} + 6\left(\frac{4}{160}\right) + 6\left(\frac{4^2}{160^2}\right)\right] = 34.2 \times 10^6.$$

Beams (Modified Stiffness in Center Bay Due to Symmetry Requiring Analysis of Only One Half of Frame—Eq. 14*c*).—

$$\bar{S}_M = \frac{2\ (3{,}550) \times 10^6}{160\ (1 + 0.7877)} = 24.8 \times 10^6.$$

Second-Story Columns.—

$$\bar{S}_M = \frac{2\ (3{,}321) \times 10^6}{113.33}\left[2 + 6\left(\frac{3.33}{113.33}\right) + 6\left(\frac{3.33^2}{113.33^2}\right)\right] = 127.9 \times 10^6.$$

First-Story Columns (Upper End).—

$$\bar{S}_M = \frac{2\ (3{,}321) \times 10^6}{116.67}\left[2 + 6\left(\frac{3.33}{116.67}\right) + 6\left(\frac{3.33}{116.67}\right)^2\right] = 123.9 \times 10^6.$$

Proportional factors for distributing moments to ends of members are given in Table 4. The distribution may be done either directly on a diagram of the frame in the manner frequently followed or in tabular form. The solution is herein presented in tabular form (see Fig. 10), through five cycles after the initial distribution. Each cycle consists successively of: (*a*) The carry-over of moments from the previously distributed moments; and (*b*) the distribution of the new unbalanced moment at each joint to the ends of the members. The final summation of moments may be compared with the results of the solution by the slope-deflection method, and the results are seen to check with a maximum error of two in the third significant figure, or a fraction of 1%, except in the case of the smallest moment of 1.07 in-kips,

TABLE 4.—PROPORTIONAL FACTORS FOR DISTRIBUTING MOMENTS TO ENDS OF MEMBERS

JOINT 1			JOINT 2			JOINT 3			JOINT 4

Fig. 10.—Solution by Moment Distribution

Sidesway Induced by Unsymmetrical Vertical Loads

The writers have analyzed the frame shown in Fig. 11 by both slope deflection and moment distribution in order to study the effect of neglecting sidesway as induced by unsymmetrical vertical loads. Space does not permit the details of the analysis, which follows usual procedures, however. The dimensions of the frame and size of members are shown in Fig. 11 and the beam *a b* is assumed to carry a uniformly distributed load of one kip per foot. As in the previous case, it was assumed that the columns were fixed at the base, but the beam-column connections were assumed to have "50% rigidity," which corresponds to $\alpha = 1$. The results are presented in Table 5.

Although no general conclusions should be drawn from this single case, it is seen that in Table 5 sidesway could have been neglected without great

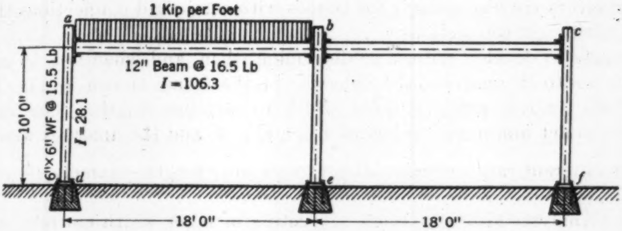

FIG. 11.—UNSYMMETRICALLY LOADED FRAME

error in the end moments. Sidesway due to vertical loads usually will be less in frames with semi-rigid connections as compared with the same frames rigidly connected, and will be further decreased in the actual structure by walls and concrete incasement.

EFFECT OF WIDTH OF MEMBER UPON ANALYSIS

In the analysis of frames, the length of each member is often assumed to be equal to the distance center-to-center of joints. The moments thus computed at the joint centers will usually be higher than the actual moment at the connection at the end of the member. This method of computation is usually on the safe side in determining end-connection moments but generally will be on the unsafe side in determining the maximum positive moment near the center of the beam.

An approximate correction is sometimes made for the effect of member width. The end moments computed in the foregoing manner are used to construct the moment diagram. The actual end-connection moment to be used in design is then taken as the ordinate to the moment diagram at the face of the column or connecting member. This method usually gives values of end-connection moments that are too low.

The error by either of the foregoing methods becomes greater as the ratio between the width of the joint and the length of the member increases. The average errors are also greater for frames with semi-rigid connections than for frames with rigid connections.

In order to develop criteria to determine when, and when not, to consider member width in analysis, the behavior of the frame shown in Fig. 12 was studied for various ratios of joint width to member length. The load was assumed to act uniformly on beams 1–2 and 3–4, and the analyses were made for four different ratios of joint width to member length—namely, $\frac{1}{15}$, $\frac{1}{12}$, $\frac{1}{9}$, and $\frac{1}{6}$. Analyses also were made neglecting member width entirely, and the method of arbitrary correction previously outlined was tried also. The analyses were made both for a frame with rigid connections and for a frame with continuous columns but with semi-rigid beam-to-column connections. All of the analyses were made by the method of moment distribution.

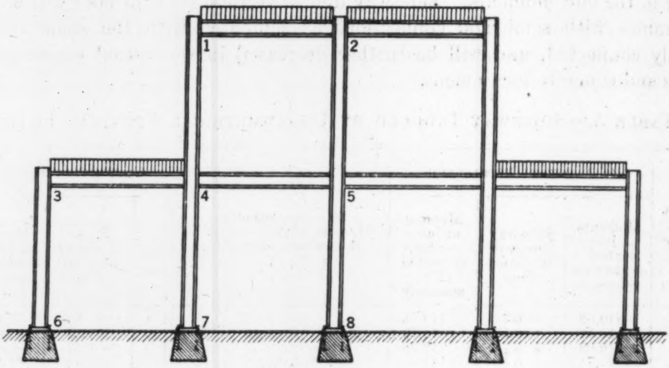

FIG. 12

Special note should be made of the length of the columns in relation to beam depth. The methods herein presented to take account of width of joint are based on the assumption that the interior of the joint may be considered infinitely rigid in comparison with the bending stiffness of the member. In the case of a beam framing into a column, this assumption seems reasonable, particularly if the column runs through the joint without a splice. In the case of the continuous column, however, the connection moments are introduced by concentrated lateral forces acting at the top and bottom of the beam in the type of connection shown in Fig. 2(*b*). In such a case it may be shown that nearly correct results may be obtained for the moments in the column by assuming a length correction for the column of one third the beam depth at each end instead of one half the beam depth. This correction was made in the analyses under consideration and was found to give good results in actual frame tests.

The results of these studies are shown in Fig. 13 for the frames with rigid and semi-rigid connections, respectively. The solid lines give the percentage of error of moments determined with a neglect of joint width as compared with corresponding moments correctly computed at the face of the joint. The broken lines give the percentage of error resulting from the arbitrary correction for joint width by neglecting it in the analysis but using the ordinate of the moment diagram at the face of the joint.

It is noted in Fig. 13 that the maximum percentage of error occurs in the case of the large end moments in the loaded beams at joints 1 and 4. It also may be seen that the errors are usually larger in the frame with semi-rigid connections than in the frame with rigid connections. The errors are appreciable even for low ratios of joint width to beam length. In the case of a one-to-twenty ratio, for example, the error may be as high as 20%, with the average error about 5% for the rigid frame and as high as 25%, and with an average error close to 10% for the frame with semi-rigid connections. As the ratio of joint width to beam length increases, the errors become increasingly larger.

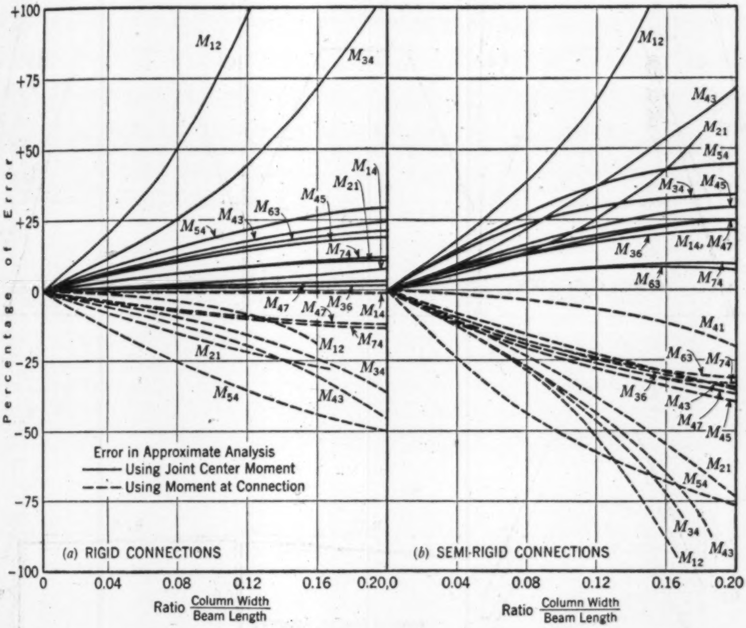

FIG. 13.—PERCENTAGE OF ERROR IN CONNECTION MOMENT, NEGLECTING MEMBER WIDTH

A fairly close approximation for the moment at the connection is obtained by neglecting joint width in the analysis and using, as the connection moment, the moment halfway between the connection and joint center.

COMPARISON BETWEEN THEORETICAL ANALYSES AND TEST RESULTS

In order to compare the results of analyses with the actual behavior of building frames, two full-size, all-welded, model building frames were con-

(*c*) FRAME 1; CRITICAL LOADING (BEAMS B2L, B1C, AND B2R)

(*d*) FRAME 2; CRITICAL LOADING (BEAMS B2L, B1C, AND B2R)

OBSERVED MOMENTS, FOR CRITICAL CONDITIONS structed. Details of these tests have already been presented in another paper by the writers (2).

Frame No. 1 was made with beam-to-column flange connections, whereas frame No. 2 had beam-to-column web connections. The general dimensions and size of members of frame No. 1 are shown in Fig. 8 in connection with the illustrative example (see heading "Analysis by Slope-Deflection Method"), and a photograph of the same frame is shown in Fig. 9. The beam-to-column connection used in these frames consisted of welded seat and top angles, the details and semi-rigid properties of which have been described elsewhere (2). Vertical loads were applied to the frames by means of water tanks, which are shown in Fig. 9 in one of the loading positions. Each frame was braced laterally near each joint by means of flexible ties welded between columns of the frame and columns of the laboratory. These ties had reduced sections near each end that allowed the frame full freedom to bend or move laterally in its own plane but that prevented movement out of its own plane.

The computation of the moments developed during tests of the frames was made by measuring the rotation at the ends of each beam and at the joint centers by means of the 20-in. level bar which was illustrated in Fig. 3. Then the moments at the end of each beam and column could be calculated by the slope-deflection equations (see Eqs. 3).

The connection constants for typical joints in the frame were determined by means of the setup shown in Fig. 2(*b*). The experimentally determined values of these connection constants, as determined by Fig. 4, have been used in the theoretical analyses. The method of moment distribution was used and a typical analysis, taking account of the width of member, has been presented in the illustrative example.

Fig. 14 shows both the computed and experimentally determined moments for several of the critical conditions of load that were applied to the two frames. Fig. 14(*a*) shows moment diagrams for frame No. 1 with only first-floor beam loaded. Fig. 14(*b*) is for frame No. 1 with unsymmetrical loading in which only one outside second-story beam was loaded. Sidesway was neglected in the analysis but the agreement between analysis and experimental result is excellent. A comparison is made in this case with an analysis assuming completely rigid joints. The actual test results agree well with the analysis for semi-rigid joints but are widely divergent from the analysis for rigid points. It should be noted that the moments "taper out" much more rapidly in a frame with semi-rigid connections than in one with rigid joints. Fig. 14(*c*) is for a critical condition of loading. In applying the test load for this case, the order of loading was purposely unbalanced but the moments by test are in fairly good agreement with the theoretical analysis. Fig. 14(*d*) is for frame No. 2, with beam-to-column web connections, and is for the same critical loading condition as Fig. 14(*c*). The outside column connections in frame No. 2 has less rigidity than the inside, and this was taken into account in the analysis. The analysis based on the assumption that the outside joints are as rigid as the interior joints is also given, and it is seen that the test results usually fall between the two different analyses.

In general, the test results agree well with the methods of analysis which have been presented. The results also show that the test of a single joint to determine the connection constant gives a satisfactory measure of the behavior of the same type of joint used in an actual frame.

THE DESIGN OF FRAMES FOR PARTIAL RIGIDITY

The methods of analysis which have been presented in this paper obviously are not directly applicable to design. Any method of statically indeterminate analysis requires an assumed structure as a preliminary to design. To assume a building design, and then to analyze such a highly redundant structure by the methods that have been presented, would be an impractical design procedure, warranted only for very special problems.

For routine building design, a suitable method must be direct and simple in application. Such design methods have been presented by the writers in conjunction with a particular type of all-welded, beam-to-column connection (2), and in a more general article covering the application to any semi-rigidly connected structure (3). The British Steel Structures Research Committee (1) has developed design procedures for frames with semi-rigid riveted connections. In a letter dated December 26, 1940, S. D. Lash, secretary of the Subcommittee on Steel Construction, National Building Code, National Research Council of Canada, stated that simplifications in the original design method have been made in Great Britain and that similar steps are in progress in Canada.

The design procedure for the beams in welded building frames with semi-rigid connections that has been developed by the writers (2) may be outlined as follows:

1. The beams are designed by the usual procedure of computing the required section modulus for maximum simple beam moment.
2. The section modulus for maximum simple beam moment is multiplied by a reduction factor that depends on the distribution of load and relative stiffness of the simple beam and adjacent column sections. This reduction factor is obtained from a graph or simple formula and is based on the most critical combination of load possible.
3. The final beam selection is determined by the reduced section modulus found by step 2.

Although the method was developed for designing beams with welded connections, it is applicable to any frame having connections with the desired semi-rigid properties.

In computing the reduction factor, the stiffening effect of adjacent beams was neglected, and the same formula applies to exterior and interior bays. By this procedure, with end connections designed for 50% end restraint, an average saving in the weight of beams of between 15% and 20% was found possible. If greater refinement and complexity are introduced into the design procedure, the average saving in weight of beams might be raised to more than 20%.

CONCLUSION

The methods presented and corroborated by test in this paper represent a refinement in the analysis of building frames. It may be questioned whether such refinement is warranted. The concrete encasement of beams, columns, walls, and partitions, and the uncertainties of applied load, all represent indeterminate quantities which, undoubtedly, may have as great, or greater, effect upon frame behavior as does the semi-rigidity of the bare steel connection. Nevertheless, discounting these uncertainties as assets that cannot be counted upon definitely, there remains the certain dependable bare connection end-restraint. This influence can be determined and applied to the development of improved and more economical methods of design.

ACKNOWLEDGMENT

The tests of the all-welded steel building frame were part of an investigation conducted at the Fritz Engineering Laboratory of Lehigh University, at Bethlehem, Pa., in cooperation with the Structural Steel Welding Committee of the American Welding Society. Leon S. Moisseiff, M. Am. Soc. C. E., was chairman of the committee. The writers received the cooperation of Prof. Hale Sutherland, M. Am. Soc. C. E., director of the Fritz Engineering Laboratory, and Howard J. Godfrey, engineer of tests.

DISCUSSION

Maurice P. van Buren,[4] **Assoc. M. Am. Soc. C. E.** (by letter).—A basis for effecting valuable economies in certain types of structures is afforded by this interesting paper. However, one important correction to the analysis should be made. In comparing the moments at the face and at the center of a joint, consideration must be given to the reaction as a load on the structure. It does not appear that this has been included in the examples given. It can be provided for easily by the addition of a term to both Eq. 4*a* and Eq. 4*b*. At the point of inflection of the column, the reaction is uniformly distributed, and will cause a moment about the joint center of $V\,g\,b$, in which $g\,b$ is the distance from the joint center to the centroid of the half column. This moment is of opposite sense to the moments $V\,b$, and the last terms of Eqs. 4*a* and 4*b* will then read: $-\,V_{AB}'\,(1-g)\,b_{AB}$ and $V_{BA}'\,(1-g)\,b_{BA}$, respectively. The significance of this effect is apparent in the case of the flanged column illustrated in Fig. 5(*a*), for which g approaches 1, and the term involving V practically vanishes. The authors' comments on the extent to which final results will be affected is awaited with interest.

Wayne W. Smith,[5] **Leonard P. Zick, Jr.**,[6] **Juniors, Am. Soc. C. E., and Conrad C. Wan**,[7] **Esq.** (by letter).—As the authors have shown, there are reasonable possibilities for a more economical design of frame construction by considering the semi-rigidity of connections. As they have stated, their method, in practice, is too cumbersome to be used directly. Their suggested procedure using simple beam moments and reduction constants thus appears to be the most practical method of design. However, it should be emphasized that every continuous structure or frame is an individual problem and should be dealt with as such. Graphs, charts, and simple formulas may be used to simplify certain designs, but a thorough knowledge of their limitations must guide their use.

According to the authors' test results, the maximum moment developed was about 274 kip-in. (Fig. 14(*d*)). For the 10-in., 25.4-lb, I-beam used, this meant that a stress of 11 kips per sq in. was developed, a stress considerably below the elastic limit of steel. The use of the connection constant γ seems quite proper within the "design range," but as seen in Fig. 15 the constant changes rapidly beyond this range. This design range is not clearly specified in the paper. Making the logical assumption that the design range is one half the elastic limit, there is an "overload range" for which γ is no longer constant. Failure should not occur until the elastic limit is reached, which limit is the farther boundary of this overload range. Realizing that the maximum moment does not necessarily occur at the joint, the question arises as to how important is the discrepancy due to assuming γ constant when the member is stressed nearly to the elastic limit. To ignore this point may reduce the factor of safety for the member.

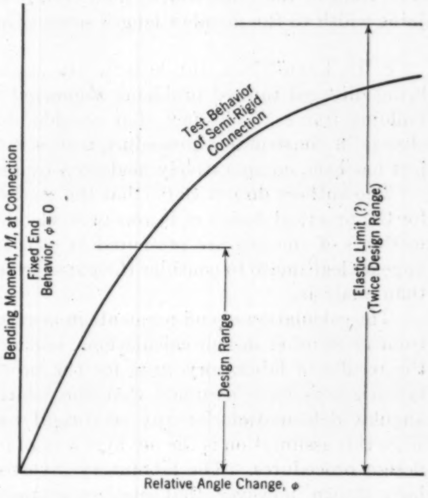

FIG. 15

It seems that the authors' suggestion of neglecting the sidesway moments due to vertical unsymmetrical loadings is contradictory to the degree of refinement in their analysis. As shown in Table 5, the sidesway moments range from 6.74 to −12.25 kip-in., which, in the latter case, amounts to a decrease of about 29%.

In the comparison by the method of moment distribution of a rigid structure and a semi-rigid structure, it is very interesting to notice the changes in the carry-over factors and the end rotation stiffness (distribution factor).

The solutions in Table 6 are for the test frame shown in Fig. 8 assuming rigid connections and neglecting joint width. The authors' results are taken from Fig. 10. As shown, the carry-over factor for the beams was decreased from the usual value of 0.5 to 0.275. Since the case of the semi-rigid beam is the opposite of the haunched beam, the results are as expected. The changes in the carry-over factors for the columns are due to the consideration of the joint width only. The results given in Table 6 for the analysis with joints 100% rigid is merely additional information. The authors have already shown the large

TABLE 6.—COMPARISON OF MOMENTS AND STIFFNESS FACTORS FOR RIGID AND SEMI-RIGID CONDITIONS

disagreement considering 100% rigid connections (see heading "Comparison Between Theoretical Analysis and Test Results").

The authors are to be commended for the close agreement between the theoretical and experimental results that they obtained. Also, in their consideration of the joint width, their results showed that for large ratios of the joint width to the member length some adjustment should be made.

S. D. LASH,[8] ESQ. (by letter).—It is gratifying to find that attention is being directed toward problems connected with the design of beams in steel building frames. The fact that considerable economies are possible without change in construction procedure makes it the more surprising that this subject has been comparatively neglected by practising engineers.

The authors do not claim that the methods presented by them are suitable for the practical design of beams in steel building frames. However, since the methods of analysis are presented as a basis for simpler design procedures, it appears legitimate to consider the paper from the point of view of design rather than analysis.

The calculation of end moments in beams with semi-rigid connections differs from most other design calculations, inasmuch as it is necessary to rely upon the results of laboratory tests for the properties of the connections. Many investigators have assumed that the relation between applied moment and angular deformation for any semi-rigid connection is approximately linear, since this assumption is the obvious way of introducing modifications of regular design procedures. The laboratory investigations referred to by the authors have shown, however, that such an assumption is incorrect for most types of semi-rigid connections. The relation between moment and angular deformation is not linear, and the behavior of a connection on first loading differs considerably from its behavior on subsequent reloadings. In an experiment on a steel frame, if the loads are applied, removed, and reapplied, measurements of strains being taken on the reloading, these strains will depend upon the reloading curves for the connections, but the total strains will be those corresponding to the initial loading curves.

Since moment-angle curves for semi-rigid connections are not linear, it would appear to be necessary to introduce some form of "limit design" when determining allowable restraining moments. Thus, for example, if a factor of safety, or load factor, of n is desired, the allowable restraining moment at working load should be $\frac{1}{n}$ times the computed restraining moment at n times the working load.

It should also be pointed out that the "connection constant γ," referred to by the authors, depends not only upon the type of connection, but also, in the case of flange-angle connections, at least, upon the depth of the beam. The constant as determined experimentally cannot be used for beams of a depth other than that used in the original tests unless suitable corrections are made.

In order to make the foregoing points more specific, Fig. 16 has been prepared using information previously published by the Steel Structures Research

---

[8] Acting Secretary, National Building Code, National Research Council of Canada, Ottawa, Canada.

Committee in Great Britain.[9] Curve (1) represents the moment-angle relationship for 4-in. by 4-in. by ½-in. flange-angle connections on a beam of 12-in. depth. Actually, this curve defines a lower limit obtained by combining the curves resulting from tests on seven riveted specimens submitted by different fabricators.

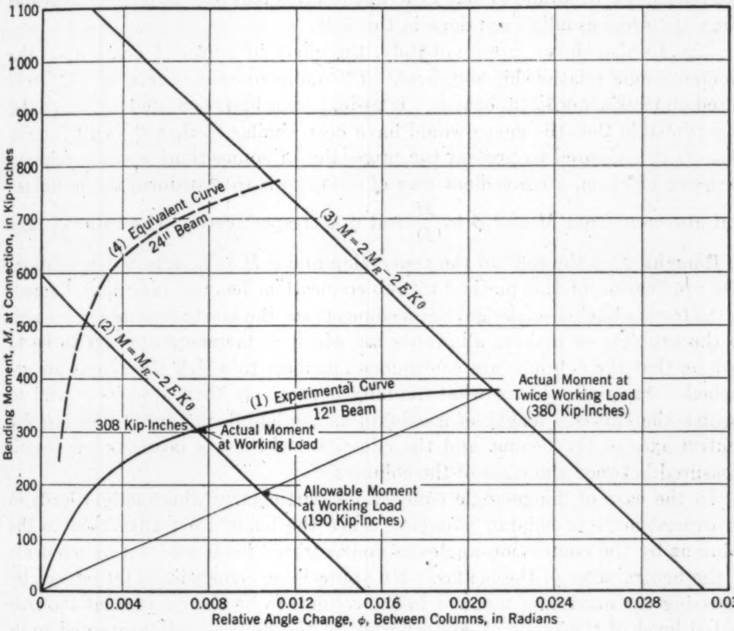

FIG. 16

For simplicity it will be assumed that a beam is attached to completely rigid columns. In such a case for symmetrical loading, the end moment may be conveniently determined by solving the equations graphically:

$$M - f(\phi) \qquad (23)$$

representing the curve of the connection; and

$$M = M_R - 2\,E\,K\,\phi \qquad (24)$$

representing the slope-deflection equation.

In Fig. 16 two lines, (2) and (3), are drawn corresponding to slope-deflection equations for two different magnitudes of load applied to a 12-in. beam 20 ft long. Line (2) corresponds approximately to a working load and line (3) to a load twice as great. In the first instance the end moment is 308 kip-in. and in the second, 380 kip-in. Thus, for a load factor of two, the allowable moment at working load should be 190 as indicated by line (5) instead of 308 kip-in. This diagram will also serve to indicate that the working range of the curve for a connection is actually quite extensive. For case shown it will extend at working loads from angular deformations of about 0.002 radians up to 0.12 radians and, if overload is being considered, up to twice these values. For this reason it is desirable to take experimental readings over a somewhat greater range than has usually been done in the past.

---

[9] Final Report, Steel Structures Research Committee, Dept. of Scientific and Industrial Research of Great Britain, H. M. Stationery Office, London, p. 282.

Fig. 16 also shows, approximately, the effect of depth of beam upon the moment-angle relationship obtained. The moment-angle curve (1) shown is based on tests using 12-in. beams. If 24-in. beams had been used in these tests, it is probable that the curve would have been similar to that shown by curve (4). If it is desired to present the properties of connections without relation to depth of beam, a convenient way of doing so is to transform the ordinates and abscissas from M and ϕ to $\frac{M}{D}$ and ϕD, respectively. The ratio $\frac{M}{D}$ may be thought of as the pull on the connection and ϕD as its linear deformation. The application of this method to web connections has not been investigated.

In frames having semi-rigid beam connections, the most reasonable approach to the problem of making allowance for width of members appears to be to assume that the columns are continuous members to which the beams are attached. After all, this is what actually occurs. It then appears logical to assume the effective length of a column as the length measured between the neutral axes of the beams, and the effective length of a beam as the length measured between the faces of the columns.

In the case of flange-angle connections particularly, this method leads to an overestimate of column moments, since the loads are transmitted to the columns by the connection angles as concentrated loads and not as moments at the neutral axes of the beams. No appreciable error will be introduced by assuming the maximum moment in the column to be the moment at the estimated level of the point of contraflexure of the flange angle connected to it. Although this correction may be worth making from the point of view of the design of the column, it is doubtful if it is worth making when considering the distribution of moments throughout a framework, since an appreciable rotation of the end of the beam may result from local shear deformation of the column in the vicinity of the connection. Results published elsewhere[10] have shown that this deformation may increase the total rotation of the column at the level of the beam by 30% or 40%.

The National Research Council of Canada has recently published Part 3 (Engineering Requirements) of the National Building Code (a model code for the use of Canadian municipalities). In this Code an attempt has been made to give some weight to the considerations mentioned by the authors at the beginning of their paper. In particular, it is required that bending moments in columns other than those supporting a symmetrical arrangement of beams of approximately equal span shall be investigated, and the stresses resulting from them shall be provided for. With this mandatory requirement is a permissive requirement stating that "where a beam is restrained at either end due allowance may be made for such restraint." The Code does not restrict the designer to any particular method for estimating moments in columns or restraining moments in beams, but acceptable methods of doing these things are given as Appendixes. A description of the method given for computing allowable end moments was published in 1941.[11]

Dean F. Peterson, Jr.,[12] Assoc. M. Am. Soc. C. E. (by letter).—The methods presented by the authors have made an excellent rational start toward a better basic understanding of what actually occurs in a loaded frame in which the members are connected in the customary way. Expressing the laboratory-determined "stiffness" of the connection in terms of the "stiffness" of the

[12] Asst. Engr., Sanderson Porter, Pine Bluff, Ark.

connecting member "opens the door" for the application of the "moment-distribution" and "slope-deflection" methods. The writer believes, however, that the most direct and simple method for solving such an elastically complex structure as a building frame with semi-rigid connections is the "flexure factor" method.[13] Using this method it is unnecessary to solve either simultaneous equations or to make the rather involved adjustments of the "moment-distribution" method. Since no mention is made of the application of the "flexure factor" method, either in the text or in the references given, it may add to the completeness of the discussion to call attention to it.

To illustrate the application of this method, the writer has chosen the simple frame of Fig. 17(*a*). The "stiffness" of any member is the moment required at one end, with the other end freely supported, to produce an angle change of unity in the direction of the end tangents. In Fig. 17(*b*) the proportionate stiffnesses of the members are determined from the $\frac{M}{E\,I}$-diagrams. Fig. 17(*c*) is the traverse of the elastic curve due to an unbalanced moment of 100 at Point *B* and Fig. 17(*d*) is the resulting moment diagram. For a vertical load of 10 kips at a point 9 ft from Point *B* the "fixed-end" moment at Point *B*, by the "moment-area" method or by Eq. 13, is 13.86 kip-ft and $M_{BC} = M_{BA} = (0.8020)(13.86) = 11.15$ kip-ft. The writer was able to check this value by means of Eqs. 4.

The writer doubts that the effect of sidesway should be generally ignored. If sidesway were allowed in his example M_{BA} would be decreased from $+ 11.15$ kip-ft to $+ 6.54$ kip-ft, and M_{AB} would change from $+ 5.55$ kip-ft to $- 6.54$ kip-ft. What would be true, however, of such buildings as powerhouses or low warehouses would probably not be so true of a multi-story office building.

The authors are to be complimented on an excellent research project. Perhaps the time will come when the designer will be able to predict to a reasonable extent what the value of γ will be for a certain connection, or, better still, be able to design a connection for a predetermined value of α.

R. W. Stewart,[14] M. Am. Soc. C. E. (by letter).—Considerable effort has been made by the authors to overcome the complexities which result when the effect of semi-rigid connections is incorporated into the computation of the bending moments in a steel frame.

Each of the methods presented has defects which render its use difficult. This may account for the authors' statement that the methods of analysis are too complex for ordinary design use, but can be made expeditious by the use of charts and diagrams in connection with simpler design procedures. It may also account for the fact that the general case, which would occur if an unsymmetrical beam having variable moment of inertia were used between the riveted joints, was not included in the scope of the paper.

A specific list of the defects in the authors' solutions is as follows:

(1) The constants used in end-moment distribution, which are based on the

---

[13] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 521.

[14] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

moment required to produce unit rotation at one end of a beam when the other end is fixed, require long series of algebraic terms to express their values if a member is affected by asymmetry or other special conditions like the yielding joints treated by the authors. A glance at the right-hand column and then at the left column (Case I) of Table 1 will disclose how the expressions for moment-distribution constants expand when conditions other than the simplest are introduced. If these constants were further encumbered by unsymmetrical tapering members between the riveted joints, the computation of α and β would become complex, making the use of the formula very tedious and difficult.

(2) The slope deflection equations (4a and 4b) are based on $K = \frac{I}{l}$-values which are applicable only to members of uniform section between joints. The introduction of unsymmetrical tapering members would add substantially to the difficulty of computing the necessary constants.

(3) The use of the authors' methods independently of a set of charts pertaining thereto would require having at hand, for reference, formulas that are too complicated to remember.

(4) The authors' methods offer no easy facility for detecting errors which may occur in computations.

The following solution of Fig. 11 entirely eliminates defect 3 attributed to the authors' methods, as any one familiar with this method of attack would not use any references to solve any of the authors' problems, except a steel handbook giving the moments of inertia of rolled beams. It greatly alleviates defect 4 in that an automatic check involving a single setting of a slide rule will verify a large portion of the solution. It alleviates to a considerable degree defects 1 and 2 by using "illustrated" member constants which are simpler than moment-distribution constants and which can be altered without difficulty to include the general case of unsymmetrical members between joints. Fig. 18(a) represents an $\frac{M}{I}$-diagram due to a moment at one end of a beam shown in Fig. 11, the other end being hinged. It requires no explanation; Fig. 18(b) is the appurtenant graph of the tangents to the elastic curves in the beam, known as a traverse of the elastic curves, in which Δ represents the curvature between joints. To evaluate ϕ, which represents the angle of yield at a joint, Eqs. 2 and 5 yield

$$\alpha = 2\,E\,K\,\frac{\phi}{M} \qquad \text{(25)}$$

For the flexure of a beam of constant section, hinged at one end, $\Delta = \frac{M}{2\,E\,K}$. For $\alpha = 1$ (which is the condition for Fig. 11), by solving each of these equations for M, it is found that $\phi = \Delta$ for the case in which Δ is the curvature represented by a triangular $\frac{M}{I}$-diagram. For Fig. 18(b), ϕ will equal the area of the $\frac{M}{I}$-diagram under the dotted line in Fig. 18(a). With this explanation and the traverse principle[15] that in traverse triangles the lengths of the sides (considered as their horizontal projections since altitudes are negligible) are proportional to the opposite angles, Fig. 18(*b*) can be readily sketched and evaluated. The difference between Figs. 18(*a*) and 18(*b*) is of interest. Fig. 18(*a*) is a moment-area diagram that cannot show joint yield angles or joint rotation angles. Fig. 18(*b*) is a traverse diagram that shows all the elements of the flexure. The moment-distribution constants in Table 1 are necessarily based on flexure due to the existence of moments at both ends of a beam which is why they become more complicated for unsymmetrical conditions than Fig. 18(*b*) which deals with a moment at one end only. The stiffness factor computed from Fig. 18(*b*) is first computed as the moment necessary to give the value of unity to the angle shown as $\frac{432}{216}\Delta$, which represents the over-all curvature in the beam. Top and bottom stiffnesses for the columns are computed by a procedure that is similar but is simplified because there are no ϕ-angles in the columns. After all stiffness factors are computed, they are multiplied by a factor which will reduce the deck stiffness to unity in order to simplify subsequent arithmetical work.

FIG. 18

The computation for Fig. 19(*a*) is a much faster procedure than the uninitiated would suspect. When the traverse computation arrives at the top of a column both column moments are obtained by one setting of the slide rule as they bear the same ratio to the moments written on column *cf* that the angle at the top of the column bears to the angle at the top of column *cf*.

FIG. 19

There is more than one way to compute sidesway moments using the traverse method. Fig. 19(*c*) represents an elastic curve traverse converted into an amplified form of slope deflection which can be applied to the two-story structures treated in the authors' paper. The key to this method is to express the values of the angles which govern the stiffnesses in terms of the θ-angles and then proceed as in slope deflection.

Table 7 shows the moments computed from Fig. 2. The check with the authors' moments is exact.

To summarize: The methods demonstrated by the authors to establish a basis for the design of structures with semi-rigid joints required the use of derived constants and derived formulas which are inherently very complex.

The use of the basic constants of flexure[16] in an orderly manner assisted by a pictorial graph of the flexure will eliminate the necessity of making reference either to special slope deflection equations or to formula for constants in an independent solution of problems of this class. ("Independent" solution means one not dependent on a set of charts and diagrams prepared by some one else. In court testimony in a building failure case the solution should be independent.)

It will also eliminate most of the anxiety regarding the possibility of errors.

JAROSLAV J. POLIVKA,[17] M. AM. SOC. C. E. (by letter).—A complete analysis of building frames with semi-rigid connections is presented in this interesting and valuable paper. The authors have corroborated their analytical methods by tests. Both methods applied (slope deflection and moment distribution) have the same disadvantage—namely, that the computations must be made separately for each type of loading, and the exact and refined method, demonstrated by the authors, becomes complex and tedious, even for such a simple case as a two-story building with three equal bays (Fig. 8). The authors agree that the method is not applicable to ordinary design. Three types of loading (Fig. 14) require the determination of sixteen unknown slopes and this number increases to forty eight for an unsymmetrical four-story building.

The writer has attempted to find the answer to three questions relating to the analysis of building frames with semi-rigid connections:

(1) How are the results affected by certain assumptions that would simplify the analysis considerably?

---

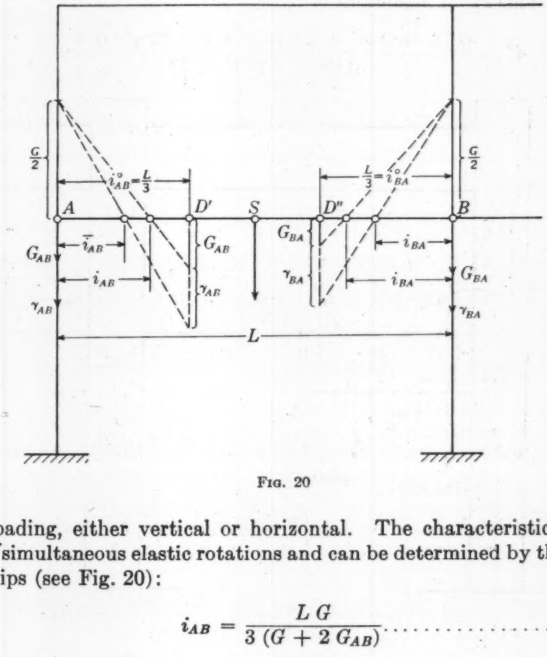
[16] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 41–44.

[17] Research Associate, Univ. of California, and Cons. Engr., Berkeley, Calif.

(2) Is it possible to determine certain constants of a given building frame that would be applicable for any type of loading?

(3) What are the short cuts of a general exact method permitting sufficient accuracy in the analysis?

Using the method of elastic weights,[18] two characteristic points for each structural member can be determined. The characteristic points are constants of the building frame and represent sufficient data to analyze the frame for any type of loading, either vertical or horizontal. The characteristic points are centers of simultaneous elastic rotations and can be determined by the following relationships (see Fig. 20):



$\frac{G}{2}$
$\overset{\circ}{i}_{AB} = \frac{L}{3}$
A
D'
S
D''
B
$\frac{L}{3} = \overset{\circ}{i}_{BA}$
$\frac{G}{2}$

FIG. 20

$$i_{AB} = \frac{L\,G}{3\,(G + 2\,G_{AB})} \qquad (26a)$$

and

$$i_{BA} = \frac{L\,G}{3\,(G + 2\,G_{BA})} \qquad (26b)$$

in which, in addition to the notation of the paper, G is the elastic weight of the beam $\left(= \frac{L}{E\,I} \right)$; and G_A and G_B are the elastic weights of the supports A and B. Angular rotations at A and B due to a unit moment are G_{AB} and G_{BA}.

For semi-rigid connections Eqs. 26 become

$$i_{AB} = \frac{L\,G}{3\,[G + 2\,(G_{AB} + \gamma)]} \qquad (27a)$$

---

[18] "Graphical Methods of Analyzing Statically Indeterminate Structures," mimeographed lectures by J. J. Polivka, Berkeley, Calif., 1940 and 1941.

and

$$i_{BA} = \frac{L\,G}{3\,[G + 2\,(G_{BA} + \gamma)]} \quad \text{(27b)}$$

In the simple case in which the width of a member is assumed equal to zero (Fig. 20), the centers of rotation D' and D'' relating to rigidly restrained supports at A and B are distant $\frac{L}{3}$ from the supports.

For a finite member width, this distance can be determined graphically, as shown in Fig. 21, or algebraically by

$$i^\circ = \frac{G\,[(l + 2\,b)^2 + 2\,b\,(l + b)] + 12\,\gamma\,b\,(l + b)}{3\,(G + 2\,\gamma)\,(l + 2\,b)} \quad \text{(28)}$$

L

Fig. 21

Using the values in the authors' example—$G = 0.04507$, $l = 160$ in., $b = 4$ in., and $\gamma = 0.01775$—the distance $i^\circ = 36.223$ in. Since the carry-over factor is

$$r = \frac{i^\circ}{L - i^\circ} \quad \text{(29)}$$

the accuracy of this method may be checked with the results obtained by the authors: $i^\circ = \frac{36.223}{131.777} = 0.27488$ (compared with 0.275 found by the authors).

In the example discussed (Fig. 8), the elastic weight of support of the beam 3-4 results in

$$G_{3-4} = \frac{G_{3-5}\,G_{3-1}}{G_{3-5} + G_{3-1}} \quad \text{(30)}$$

That is, $G_{3\text{-}4} = \dfrac{0.00878 \times 0.01008}{0.00878 \times 0.01008} = 0.00469$ and the center of resultant rotation is determined by $i = i^{\circ}\,\dfrac{G + 2\,\gamma}{G + 2\,(G_{3\text{-}4} + \gamma)} = 32.444$ in. Practically the same value is obtained using the simple term $i = \dfrac{L\,G}{3\,[G + 2\,(G_{3\text{-}4} + \gamma)]}$

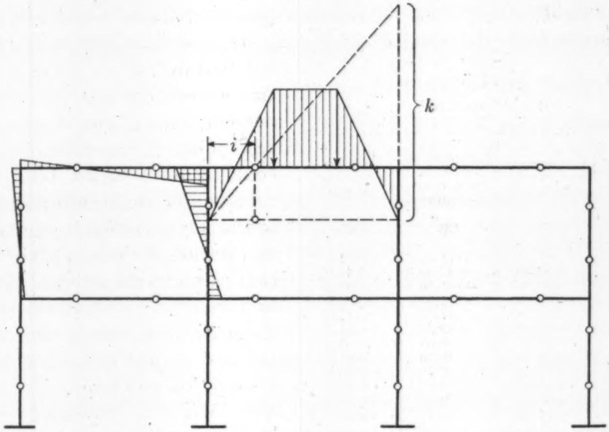

Fig. 22

$+ b = 28.058 + 4 = 32.058$ in., the difference for this short cut being only 1.2% affecting the center moment of the beam on the side of safety. This simplification eliminates entirely the complex term in Eq. 30.

Knowing the characteristic points of each structural member determining all carry-over factors, the moment diagrams for any type of loading can readily be plotted, as shown in Fig. 22.

Bruce Johnston,[19] Assoc. M. Am. Soc. C. E., and Edward H. Mount,[20] Esq.—The worth-while discussions contributed to this paper are appreciated.

Mr. van Buren assumes uniform distribution of the beam reaction in the column at a point of inflection and then concludes that the "reaction as a load on the structure" should be considered to act at the centroid of the half-column width adjacent to the beam. This would produce a moment at the joint center equal to "$V\,g\,b$, in which $g\,b$ is the distance from the joint center to the centroid of the half column." If a complete free-body diagram is drawn of the end of the beam, extended just to the column center line, it will be obvious that the moment $V\,g\,b$ is balanced by an equal and opposite moment resulting from normal stresses acting on the vertically cut section of the column web. These stresses are in equilibrium with the section of the column cut away from the imaginary free body.

---

[19] Engr., Bureau of Yards and Docks, U. S. Navy, Washington, D. C.

[20] Formerly Am. Welding Soc. Research Fellow at Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

It should be emphasized that the "hypothetical" moment at the joint center is a pure fiction, created simply for convenience of analysis, as a result of which moments are balanced at the joint center without separate consideration of the shears. The actual distribution of stresses acting in and around the joint is very complex. Exact stress analysis is out of the question and the general behavior of the connection in so far as it affects frame behavior is of more importance than a complete knowledge of stresses.

In a "rigid" frame joint, the reaction stress introduced into a column by a beam (apart from the moment producing stresses) would be uniformly distributed over the column cross section a short distance below the connection; but, in the case of a semi-rigid joint, the reaction of the beam could cause a slight tilting of the column and would shift the resultant of the column stress (again assuming no rotation of the end of the beam—that is, no frame action). The reaction would not shift all the way from the center to the column face, but this amount of shift makes a convenient assumption and happens to coincide with Mr. van Buren's suggestion. Table 8, Col. 2, presents the results of an analysis of the frame as loaded in Fig. 8, giving the results of the writers' original analysis taken from Table 3. Col. 3 is for the analysis with column reactions assumed at the connection face (as suggested by Mr. van Buren for flanged columns), and Col. 4 gives moments actually determined by test. The results are not very consistent, but may be compared on the basis of the following percentage of summed differences:

TABLE 8.—COMPARISON OF MOMENTS

Location, joint and member (1)	Connection moment, by Table 3 (2)	Connection moments, revised assumptions (3)	Average moments, by test (4)
1-2	−1.86	−1.36	−1.9
2-1	+33.50	+27.83	+41.9
2-7	−96.49	−101.10	−103.5
3-4	−109.00	−111.57	−102.9
4-3	+104.18	+107.50	+117.0
4-8	−18.46	−15.28	−21.3
1-3	+0.65	+0.68	+1.6
3-1	+55.59	+46.79	+61.5
3-5	+74.46	+62.76	+70.9
5-3	+38.82	+31.97	+28.7
2-4	+86.18	+72.47	+89.1
4-2	−21.46	−16.74	−32.8
4-6	−88.20	−74.69	−88.5
6-4	−45.99	−38.05	−37.2

$$\frac{\Sigma(\text{Difference between Col. 4 and Col. 3 or Col. 2})}{\Sigma\ \text{Col. 4}} \times 100$$

This percentage of error in the summed differences gives most weight to the moments of largest magnitude. The percentage of the summed differences is 9.95% for the writer's original analysis (Col. 2), and 15.05% for the assumption of column reaction at column face (Col. 3).

Although the analysis assuming column reaction at column face appears to be definitely less in agreement with test results, it is perhaps more important that the difference between the two is less than the percentage of error in the summed differences by the writers' original analysis. It should be added that the percentage of error in the summed differences of a "rigid frame analysis" is 58.61% (see analysis in discussion by Messrs. Smith, Zick, and Wan). Obviously, no analysis, however complicated, can ever account for variations in fabrication, and all of the other factors that affect the behavior of the actual bare frame, to say nothing of what finally happens in the actual building when cross framing, fireproofing, walls, and partitions are added. Nevertheless, the behavior of the bare frame represents a dependable minimum on which to base a more rational design procedure than that commonly used at present.

Messrs. Smith, Zick, and Wan, in their discussion, state: "It seems that the authors' suggestion of neglecting the sidesway moments due to vertical unsymmetrical loadings is contradictory to the degree of refinement in their analysis." The writers' statement was not intended to apply to analysis but rather to design, and particularly to design of sections of multi-story tier buildings where enough duplication and regularity make semi-rigid design a practicable possibility. In such cases local tendencies toward sidesway will be absorbed largely by adjacent parts of the building frame. For example, the agreement between test results and theoretical analysis for the unsymmetrical loading in Fig. 14(*b*) should be noted. Sidesway was neglected in this analysis. Hence, refined methods of analysis may be used to show that sidesway in some cases may be neglected in simplified and necessarily less refined procedures for design. In cases where sidesway affects analysis to an appreciable degree, as in the illustrative example, Fig. 11, there probably would not be enough duplication of structure to make actual design for semi-rigid behavior an economical procedure.

Mr. Lash provides a stimulating discussion on the subject of design. Messrs. Smith, Zick, and Wan also discussed the design aspects of the nonlinear relation between moment and angle change in a semi-rigid connection. The general subject of design is one that requires much more study before complete, simple, and practical rules may be specified for all load conditions, types of structure, and connection. The writers avoided this subject, their primary object being to set up methods of analysis that might be used as a basis from which to build rational procedures of design. One of the writers, in collaboration with Robert A. Hechtman, Jun. Am. Soc. C. E., has presented elsewhere a simple approach to the design problem (3).

Mr. Hechtman, in collaboration with one of the writers, recently completed a program of tests on forty-seven different riveted beam-column connections with beam depths ranging from 12 in. to 24 in. These tests have been sponsored at Lehigh University by the American Institute of Steel Construction. Preliminary studies of these test results indicate that the procedure of estimating the behavior of a 24-in. beam connection from test results obtained with a 12-in. beam connection is misleading, if not entirely unsatisfactory. This procedure was used in the reports of the Steel Structures Research Committee of Great Britain, as illustrated by Mr. Lash in Fig. 16. The M-ϕ relationship of a top and seat angle beam connection is influenced by size and arrangement of rivets, thickness of seat and top angles, thickness of beam and column flanges, and other factors, many of which cannot be similar in the 12-in. and 24-in. beam connection because of practical design requirements.

The beam lines for symmetrical loads, as shown by Mr. Lash in Fig. 16, originally suggested as a criterion of design requirement by Cyril Batho,[21] have been used to advantage in reporting recent tests of welded beam connections.[22] These tests and later tests now in progress indicate the possibility of contriving welded semi-rigid connections that will develop nearly linear behavior up to a moment which gives an adequate factor of safety.

---

[21] "Investigations on Beam and Stanchion Connections," by C. Batho and H. C. Rowan, Second Rept., Steel Structures Research Committee, Dept. of Scientific and Industrial Research of Great Britain, H. M. Stationery Office, London, pp. 61–137.

It should be noted that the "beam line" shown by Mr. Lash in Fig. 16 is for "constant beam load." If the semi-rigid connections are actually considered in design, the load capacity of the beam will increase as the connection stiffness increases. If the columns are assumed not to rotate, and the semi-rigid connections are counted upon to their full capacity, the design will be for "constant maximum beam stress," and the design requirements are then more severe than for "constant beam load."

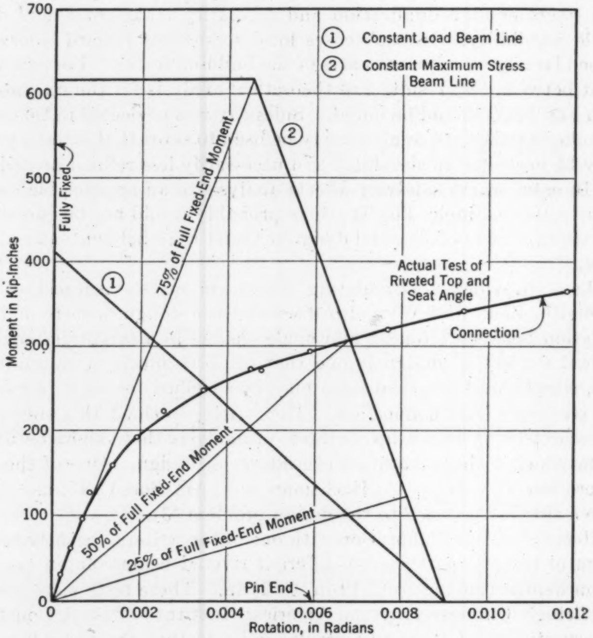

FIG. 23.—DESIGN REQUIREMENTS FOR 12 WF 25 BEAM

The beam-line equation for "constant beam load" has been noted by Mr. Lash in Eq. 24 ($M_R = M + 2\,E\,K\,\phi$). Eq. 24 is plotted as curve (1) in Fig. 23 for a 12 WF 25 beam (12-in., 25-lb wide flange I-beam) for $\frac{l}{d} = 20$. For the condition of constant maximum beam stress, M_R is not a constant. If the maximum design stress of 20 kips per sq in. is developed, the following equation gives M_R for the uniformly loaded beam:

---

[22] "Tests of Miscellaneous Welded Building Connections," by Bruce Johnston and Gordon R. Deits, *The Welding Journal*, Vol. 21, No. 1, January, 1942, Research Supplement, pp. 5-s to 27-s.

$$M_R = \tfrac{2}{3}(20\,S + M) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

in which S is the section modulus of beam. Substituting Eq. 31 in Eq. 24, the beam-line equation for "constant maximum beam stress" is obtained:

$$M + 6\,E\,K\,\phi = 40\,S \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Eq. 32 is plotted as curve (2) in Fig. 23. The beam line, curve (2), is cut off by a horizontal line corresponding to joint rigidities equal to or greater than 75%, in which case the end moment governs the design. The experimental curve in Fig. 23 represents results of a typical connection test of a riveted seat and top angle connection, using a 12 WF 25 beam, as tested at the Fritz Laboratory.

In the foregoing, the columns are assumed not to bend or rotate at the joint. When column bending due to unbalanced beam loads is allowed for, the design loads will be less than assumed in Eq. 32. In such cases the design requirements usually will be somewhere between beam curves (1) and (2), Fig. 23. The beam line for uniform load and "constant maximum stress," therefore, seems to be a good criterion of connection performance for actual semi-rigid design.

When column bending is allowed for, there may be some question as to whether or not it is necessary to penalize the design load by the straight-line construction shown in Fig. 16, drawn from the "twice working load" beam line, because the design requirements will be modified by column rotation. However, in order to maintain a safe structural load factor, some reduction in design value must be made if the M-ϕ curve is decidedly nonlinear up to a beam line constructed on the basis of (working load) × (factor of safety). Mr. Lash has suggested a factor of safety of 2, in Fig. 16, and this is a conservative value.

The discussions by Messrs. Peterson and Stewart both claim advantages for the "flexure factor" method of analysis as compared with moment distribution or slope deflection. In Table 7, Mr. Stewart[13] shows an exact check by the flexure factor method with the writers' illustrative example, Fig. 11.

Any designer who is actively engaged in analyzing continuous structures will be well repaid by a thorough study of the flexure factor method, as is attested by the discussions of Mr. Stewart's paper[13] by a number of designing engineers who have used it in their work. The method is particularly advantageous if variable load conditions are to be considered on any one structure.

In spite of the advantages of the flexure factor method as an analytical tool, the ultimate application to semi-rigid design probably will be made only in cases of multi-story buildings with regular repetition of bays, or in the case of a large factory with similar repetition of design in roof construction. In the case of the multi-story building, the design probably will be made by means of standardized connections and simplified design rules, and the designer will not make a complete analysis at all, either by the writers' method or by Mr. Stewart's method. It appears to the writers that the slope-deflection method will be the most suitable in establishing general design formulas for typical and limiting conditions, thereby leading to simplified design rules or charts.

Mr. Polivka has shown, in his well-written discussion, how readily the graphical method of "characteristic points" lends itself to the semi-rigid analysis problem. His discussion, like Mr. Stewart's, is a valuable addition to what might be termed a symposium of different methods of semi-rigid frame analysis. Perhaps it would be better to say "techniques" than "methods," since all are merely special ways of determining terminal moments in framed members, with the fundamental basis in each case being expressed by

$$\frac{M}{E\,I} = \frac{d^2y}{dx^2} \quad \text{(33)}$$

which is the well-known equation of the bent beam.

In conclusion, the writers wish to emphasize that the important problem is not analysis, but design. More rational methods of analysis are significant only to the extent that they result in more rational methods of design, thereby reducing the "factor of ignorance" and effecting greater economy in the use of materials.

SURFACE RUNOFF DETERMINATION FROM RAINFALL WITHOUT USING COEFFICIENTS

By W. W. Horner,[1] M. Am. Soc. C. E., and S. W. Jens,[2]
Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. L. Harrold, C. E. Ramser, LeRoy K. Sherman, A. J. Schafmayer, C. S. Jarvis, G. W. Musgrave, F. L. Flynt, W. I. Hicks, Albert S. Fry, and W. W. Horner and S. W. Jens.

Synopsis

In hydraulic engineering practice, the relation between rainfall and runoff has generally been represented as a ratio or coefficient. It has been recognized that the form of this relationship should be "rainfall minus losses equals runoff." Heretofore the inadequacy of hydrologic data has discouraged attempts to evaluate losses as they occur during a storm period. In this paper the writers call attention to the recent improvement in hydrologic data with respect to precipitation and stream flow, and to the information with respect to infiltration that has developed from the research program of the U. S. Department of Agriculture; and they outline a method of applying this information to the evaluation of surface runoff from precipitation data without the use of a coefficient. The method is presented as being generally applicable to all drainage basins, and is described in detail as it would be used in urban storm drainage.

PART I.—GENERAL PRINCIPLES

Introduction

Fig. 1 shows two patterns of one-day storms, each producing a total precipitation of 6 in. On these storm patterns have been indorsed the values of infiltration capacity that might prevail in a midwestern drainage basin, under average agricultural land use, in midsummer. The two infiltration capacity curves are basically the same, but appear differently on the two diagrams as a result of the difference in precipitation pattern.

Note.—Published in April, 1941, *Proceedings*.

[1] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

[2] Associate Consultant, W. W. Horner & H. Shifrin, St. Louis, Mo.

The shaded area represents, by hourly mean values, the excess of precipitation rate over infiltration capacity rate, and therefore the hourly production of excess rainfall. With some allowance for interception and depression storage, this will become an evaluation of surface runoff, as it is produced.

The mass values of surface runoff are materially different on the two diagrams. Obviously these two storms on the same area and in the same season will produce materially different values of flood flow. Engineers have been accustomed to attempt to express the volume of surface runoff from a storm of particular duration as a percentage of the total rainfall. Fig. 1 indicates why no single percentage or coefficient can be highly significant. It indicates further why these coefficients might be expected to have a wide range of values, even in a single season of the year.

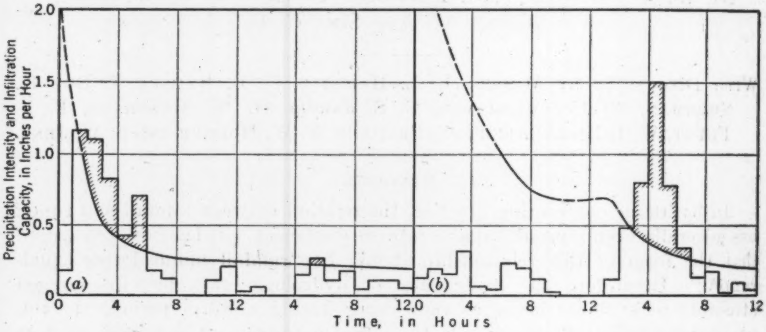

Fig. 1

The hourly variation in surface runoff production is quite different in the two cases; it is readily imaginable that the peak rates of surface runoff which these storms would produce in any stream system would be quite different, and it would follow that any attempt to express peak or crest runoff rate as a percentage or coefficient of the rainfall rate, for some critical time, would also result in a wide range of coefficients even in a single season of the year.

Hydrologic Data

The efforts of the engineering profession to develop, from available data, coefficients of runoff, either by volume or rate, have been due largely to the fact that, until recently, insufficient hydrologic data have been available to justify an attempt at more refined procedure.

Precipitation information was not formerly collected or published with any great consideration for the needs of engineering practice. For large areas in the United States, the only rainfall data available have consisted of the published records of daily totals. Recording rain gages existed at the first-order stations of the U. S. Weather Bureau, but the records were not published in detail.

Where excess rainfall is to be determined by subtracting infiltration rates from precipitation rates, the engineer must know the pattern of precipitation occurrence; if he is to utilize hourly rainfall rates, he must do it with an understanding of the manner in which precipitation actually occurs, on the average within the hour. The result of the study by Erwin R. Breihan,[3] Jun. Am. Soc. C. E., reproduced as Fig. 2, may be startling to the engineer who has been accustomed to using hourly mean rates. Such an engineer will have some difficulty in assimilating the idea that, on the average, half of the rainfall occurring within an hour actually falls at intensities equal to, or exceeding, twice the mean hourly rate.

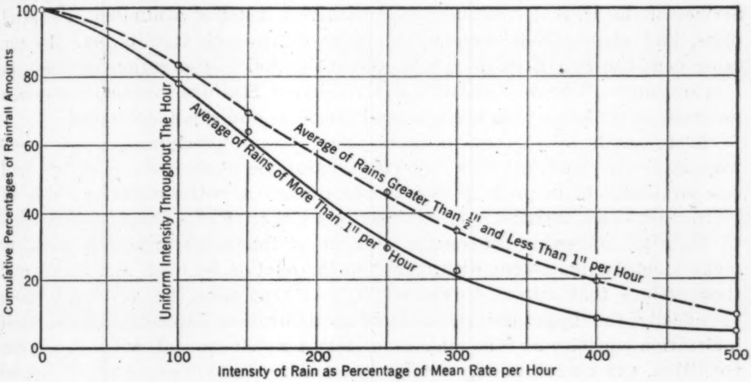

FIG. 2.—RELATION OF PRECIPITATION INTENSITY WITHIN THE HOUR, TO MEAN HOURLY RATE

The tremendous expansion of both public and private work in the hydraulic field, and the corresponding expansion of the engineering practice in this field, have produced a continuing pressure for better information, which has finally resulted in an extension of the basic data-collection services and installations. The expansion of the network of recording rain gages by the Weather Bureau and other agencies, and of the stream gaging work of the U. S. Geological Survey and of the states, has multiplied hydrologic stations and has resulted in a great increase in the number with recording equipment. With the wealth of accurate information at hand, it is to be expected that engineering practice itself will be reorganized, and that hereafter the design of important hydraulic structures should not, and need not, be based on crude over-all general relationships in the hydrologic field.

INFILTRATION

Hydraulic practice has recognized that flood flows represent a less volume of water than the related precipitation, because a considerable part of the precipitated water infiltrates into the soil. Prior to 1920 there was no appreciable body of derived data that gave quantitative values of infiltration "loss" in detail.

---

[3] *Civil Engineering*, May, 1940, p. 303.

The research of the Miami Valley Conservancy District, particularly that related to the small control plots, revealed the possibilities of securing new information and better ideas of rainfall-runoff relationships through studies on such small segregated areas.

Under the inspiration of the Miami example, one of the writers, in 1921, arranged for a series of small plot studies on plastic clay soils on the Washington University campus at St. Louis,[4] Mo., and about 1930 conducted similar studies on the Texas black soils, at Dallas.[5] As early as 1922, the Forest Service of the U. S. Department of Agriculture installed a number of control plots, and about 1933 extended this type of research installation. In the same year the Soil Erosion Service (later the Soil Conservation Service), in cooperation with State Agricultural Experiment Stations, began its research program on a nation-wide basis, using both plots and small watersheds.

As to nearly all of these projects, the values of precipitation and runoff were originally analyzed in an effort to determine coefficients of runoff, and comparatively little progress was made toward a better understanding of infiltration characteristics. It remained for Robert E. Horton,[6] M. Am. Soc. C. E., after reviewing the results of some of this earlier research work, to make a definite statement with regard to the relation between infiltration and these values that appear to control it. At that time, he developed more specifically the hypothesis of a limiting infiltration capacity, and defined infiltration capacity as "the maximum rate at which the soil, when in a given condition, can absorb falling rain." Later, Mr. Horton[7] presented his initial development of the theory of overland flow as related to surface detention. It is interesting that as late as 1935 he assumed that infiltration capacity might be satisfactorily approximated as having a constant uniform value during the first hour or two of a precipitation period.

During the four years (1937–1941), the basic information needed for a better understanding of infiltration capacity became available out of the extended research program of the Department of Agriculture, and values of infiltration capacity are derivable as secondary data from possibly as many as 100,000 controlled experiments. Although a tremendous amount of analytical work must yet be done before this mass of secondary data can be produced and published so as to cover conditions, reasonably, in the United States, it is possible at this time to secure and analyze such parts of this information as may be pertinent to a particular problem.

Character of Infiltration-Capacity Curves

Characteristic curves of infiltration capacity, such as have been found to be derivable from different types of basic data,[8] are shown in Fig. 1. Fig. 3(*a*) shows a graph of infiltration capacity under artificially applied precipitation on grass, on an old hydraulic fill area near Washington, D. C., one day after this plot received a rain of 3.50 in. per hr. Fig. 3(*b*), similarly, was prepared from one of the plots tested at Washington University in 1923.

Fig. 4 also shows infiltration capacities at Edwardsville, Ill., for the storms of March 30, 1938. Antecedent rainfall consisted of 0.66 in. which fell on March 28, with a gross duration of 11.75 hr (6.5 hr net). The 49.95-acre watershed was a poor pasture with grass and weeds 6 in. to 8 in. high; 61% of the soil is Bogota silt loam; surface slopes vary between 0.8% and 30%.

The efforts of the engineering profession to express the relationship between rainfall and surface runoff in terms of coefficients of runoff, involving either volumes or rates, have been due to the fact that until recently sufficient hydrologic data have not been available to permit visualization of their relationships in more detail.

It will be noted that these curves all have characteristically similar shapes, the value of infiltration capacity being relatively high in the beginning of precipitation, decreasing rapidly as precipitation continues, and tending to reach rather definite minimum values, for a particular precipitation period, within a time of 2 to 20 hr. The shape of the early segment of these curves is particularly important when this information is to be applied to the calculation of runoff from small areas under intense precipitation. Where the problem involves high intensity storms of several hours' duration, relatively high initial values may not greatly affect the volume of total runoff. Nevertheless, in the Edwardsville storm of July 17, 1938, the first 8 hr of rainfall, amounting to 1.5 in., produced no runoff.

The production of such characteristic curves as those in Figs. 3 and 4 represents a long advance over the earlier conception of uniform infiltration capacity. Hydrologists are not as yet fully agreed as to the mechanics of infiltration that result in the production of high initial values and the steady reduction toward a constant minimum, and this matter is being investigated intensively.

The results of research indicate that: (1) Infiltration capacity varies little with surface slope; (2) it probably varies materially with soil porosity and with soil moisture, possibly with soil moisture deficiency below field capacity; (3) it may change rapidly with an alteration of soil surface condition such as may occur under the puddling action of rain impact, or under erosion and inworking of fines where the soil is not protected by good vegetal cover;

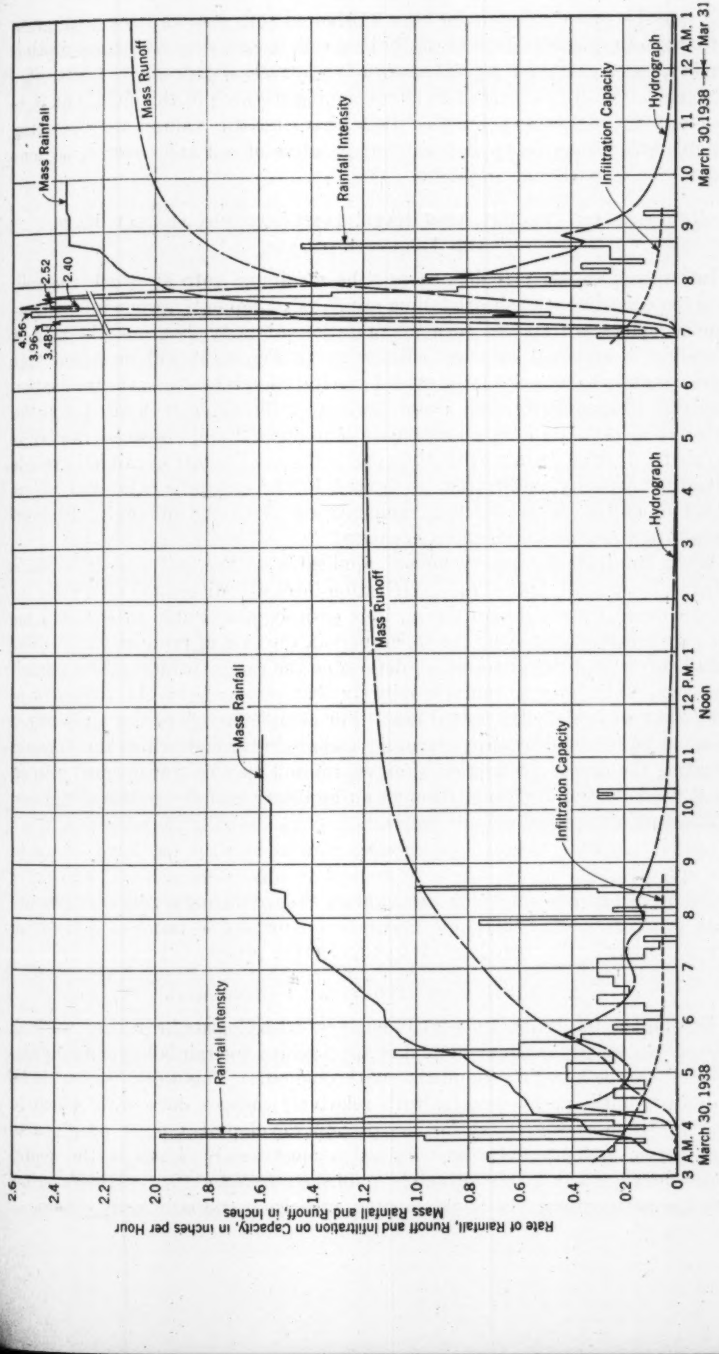

FIG. 4.—STORMS OF MARCH 30 AND 31, 1938, AT EDWARDSVILLE, ILL.

(4) it may be quite different for bare cultivated soils as compared with grass or other good vegetal cover; and (5) for bare soils it may vary with precipitation intensity, but under good vegetal cover it is relatively independent of intensity.

Much is yet to be learned from continuing research in this field, but it is important to engineering practice that characteristic values are becoming available which may be applied as representative of soil and cover conditions encountered in particular problems.

RELATION OF PRECIPITATION RATE, INFILTRATION-CAPACITY RATE, AND EXCESS RAINFALL

Infiltration capacity is defined as "the maximum rate at which the soil, in a given condition, can absorb falling rain." Consequently, when infiltration-capacity values are applied to a precipitation-intensity diagram, the rate of infiltration is apparent at once. Referring to Fig. 4, it will be noted that between certain time periods, the rate of precipitation is less than the infiltration capacity. Consequently, for those periods, infiltration is limited by the precipitation rate. All the precipitation is infiltrated and no excess rainfall is produced. During certain other time periods where the rate of rainfall exceeds infiltration capacity, infiltration is limited to the capacity rate, and excess rainfall or supply is produced in amounts equal to the difference between precipitation rate and infiltration capacity.

When infiltration-capacity curves applicable to the soil and cover in a drainage basin are applied to precipitation-intensity diagrams, either for an actual storm or for a design storm, it is entirely practicable to compute for time increments, throughout the storm period, the rate of production of excess rainfall; or, in equivalent terms, to determine the rate at which excess rainfall will occur. This process removes entirely that phase of the old coefficient of runoff that was related to actual loss. For complete engineering application, this must be followed by supplementary technique through which the diagram indicating the rate of production of excess rainfall may be transformed into an actual flood flow hydrograph, through an application of the unit hydrograph, pluviograph, or channel storage methods.

Infiltration has ceased to be a vague phenomenon; it has been shown to have quantitative rate values with respect to any particular soil and cover condition; the manner in which these values change during a period of precipitation is determinable; therefore, infiltration expressed in terms of infiltration capacity may now be introduced into engineering practice.

APPLICATION TO HYDRAULIC ENGINEERING

During the ten years, 1931–1940, engineer-hydrologists have been working to develop a strictly rational method of approaching the rainfall-runoff relationship that can be based on sound theory throughout. This work has had to be conducted, until quite recently, with relatively meager data with which to test it. Much of the credit for the present development must be given to Mr. Horton, and probably the publication most nearly classic to the course of this development is his privately published *Bulletin 101.*[7] However, his work has been extensively complemented, criticized, and refined by others.

The results of research in this field have been presented in publications of the Department of Agriculture, or cooperating State Experiment Stations, of the U. S. Geological Survey, and in the *Transactions* of the American Geophysical Union, Section of Hydrology. A reading of selected papers from the latter for the period 1934 to 1940 gives an adequate perspective of the investigational work that has been done. As yet there has been no presentation to engineering practice of a definite technique through which the new principles and newly derived data may be applied to the evaluation of surface runoff under specific conditions.

The writers have recently had the opportunity to study and develop a methodology for such an application, first for small areas, conventional in character, at the Washington (D. C.) National Airport, and second for a natural drainage basin of about 800 sq miles. Out of the first experience there has been evolved a methodology presented in this paper as applicable to the determination of surface runoff from urban areas. Out of the second experience has come a clearer concept of a satisfactory procedure for large natural drainage basins.

The essential stages involved in this procedure are as follows:

I—Delineation of the precipitation pattern from which surface runoff is to be evaluated;
II—Choice of basic curve of infiltration capacity;
III—Adjustment of infiltration capacity values to antecedent conditions and precipitation pattern;
IV—Determination of the rate of production of excess rainfall;
V—Interception, depression storage, and infiltration out of surface detention; and
VI—Translation of mass surface runoff to hydrograph form.

I—Delineation of the Precipitation Pattern from Which Surface Runoff Is To Be Evaluated.—This pattern may be set up either in the form of a rainfall intensity diagram or of the mass curve. In the latter form the relations of precipitation and infiltration capacity are not so readily visible from hour to hour. The writers much prefer to show precipitation as an intensity diagram. For small drainage areas it is essential that this diagram be closely representative of the rainfall intensity as it actually occurs. In the illustration in Part II, a time unit of 10 min has been used and this appears to be sufficiently refined and generally satisfactory. For such small areas, retention and infiltration, out of surface detention reached significant amounts and must be evaluated separately.

For large natural drainage basins, the appropriate time unit will depend somewhat on the character of the available rainfall data. For such large areas precipitation pattern should be set up at normal Thiessen centers. At the points usually chosen for such centers generally only daily rainfall amounts are available, although often with observers' notes as to the beginning and end of heavy precipitation. It is necessary to transform this information into the most probable intensity pattern, and this must be done through comparison with the nearest available recording gage records. Obviously, if there are no records of hourly rainfall available within a reasonable distance from such Thiessen centers, it would be useless to attempt preparation of a detailed pattern of precipitation intensity at those points, and time units as great as 3 to 6 hr may be the smallest that are justified. Where the data permit, however, the pattern should be set up in at least hourly amounts.

II—Choice of Basic Curve of Infiltration Capacity.—Information with respect to land use is now quite readily available for most parts of the United States in the form of aerial photographs. Using such photographic information, the percentage of the land under any particular type of vegetal cover, such as cultivated land, pasture land, woodland, etc., may be readily determined for any drainage basin or any part of such area. Soils maps are also available for a large part of the United States. Using both types of information, it is not a difficult matter, by well-devised sampling, to take an inventory of land use and soil for a complete drainage basin of considerable size. From the results of the research programs, basic infiltration capacity curves may be selected that will be satisfactorily representative of any particular combination of soil and cover under specific seasonal conditions.

III—Adjustment of Infiltration-Capacity Values to Antecedent Conditions and Precipitation Pattern.—Although, for any soil, cover, and seasonal condition the graph representing the march of infiltration-capacity values appears to have a quite definite form under continuous excess rainfall, nevertheless, the appearance of these values during a particular precipitation period will vary with the following:

(*a*) The initial soil moisture and soil condition will vary from storm to storm, and a wide variation of initial values of infiltration capacity may be expected. For very dry, open, or cracked condition of the soil, the initial values may exceed 4 in. per hr; for wet or plastic soils, it may be as low as 0.2 in. to 0.3 in. per hr. The writers have found that for any one soil these values are responsive to antecedent precipitation, and show a fair correlation with antecedent infiltration when expressed in amount and elapsed time since occurrence. A study of a number of infiltration capacity curves produced under different antecedent conditions makes possible a reasonable choice of the initial value to be used.

(*b*) Referring to Fig. 3 it will be noted that, except for the first ten minutes, precipitation exceeded infiltration capacity. The graphs of infiltration capacity are typical of those derived from infiltrometer test runs and are representative of the march of values, throughout time, in which infiltration is continually occurring at capacity rates. Very nearly the same curves occur under natural precipitation during compact storms starting at high intensity such as the first storm shown in Fig. 4. For storms in which the precipitation rate in the early part is less than the infiltration-capacity rate, the same values of infiltration capacity will occur, but at some later time in the course of the storm.

To permit a satisfactory relation of infiltration-capacity values to precipitation rates for any particular storm pattern requires a knowledge not only of the normal capacity curve such as that in Fig. 3(*a*), but also as to where, in time, these values will appear under intermittent or varying precipitation. The required adjustment can be made from an examination of a good series of such curves derived from small watershed data under widely different rain patterns; or it may be approximated from infiltrometer tests designed for that purpose. For the latter tests, precipitation would not be applied continuously at excess rates; the tests would include several series having intervals at lower rates and also varied intervals during which no precipitation is applied.

For light open soils, the writers have found that an approximate adjustment of infiltration capacity rates to the time of occurrence may be made on the basis of mass infiltration as illustrated in Part II (see heading "Infiltration Capacity"). For soils of high clay content where the decrease in infiltration capacity rate is not so directly responsive to soil moisture change (but may be due in part to change in soil structure such as that resulting from colloidal swell) a different type of adjustment may be required.

The type of adjustment, both as to initial and continuing infiltration capacities suggested previously, is at this time the most difficult phase of the application of the proposed methodology. With the present knowledge of the mechanics of infiltration there is no definite rule that can be formulated in allocating these values. They must be applied to each storm pattern on something of a case system in which the judgment is guided by what actually happened under conditions for which infiltration-capacity curves have been derived. In addition to study of small watershed data, the guide to judgment can also be obtained from a well-devised series of infiltrometer tests.

For large drainage basins and long storms a considerable error in the choice of initial values of infiltration capacity will have little significance. For small areas, as illustrated in Part II, this item may be of major importance. This stage of the procedure requires a thorough knowledge of infiltration-capacity values for the soils and covers involved, and a complete study of all available data is a pre-essential to the undertaking of an evaluation of surface runoff.

The procedure outlined is usable at this time for any project in which the probable expenditures involved appear to justify an extended engineering analysis. Under these conditions it can be applied with a much greater assurance of accuracy, and with the use of much lower factors of safety than one involving a choice of a coefficient of runoff. Undoubtedly out of the continuing research programs, and out of the experience resulting from applications to large drainage basins, information will develop that may be expected to simplify and clarify this type of adjustment greatly. In that the method attempts to recognize the more important controlling variables and to allocate logical values to them, it will probably never be possible to reduce it to a simple routine.

IV—Determination of Rate of Production of Excess Rainfall.—With the precipitation diagram and the infiltration capacity values adjusted as outlined, a determination of the rate of production of excess rainfall is purely a matter of the subtraction of coincident values for each of the time units utilized. These values represent the gross quantity of excess rainfall produced at the ground surface during each time unit. They are subject to some further modification as outlined in Section V.

V—Interception, Depression Storage, and Infiltration Out of Surface Detention.—Surface detention is the term now generally applied to water in transit on the ground surface. In its broadest use it includes also depression storage—that is, water required to fill depressions in the ground surface below their overflow levels. Expressed in another way, it is the depth of water that must exist on the ground surface to permit flow over the surface, toward the stream margin, inlet or other approach to the main drainage system. It is not intended to cover water actually in stream channels of appreciable size.

The effect of surface detention has long been recognized in the discussion of engineering practice, but has generally been assumed to be so highly variable and so intangible in its dimensional aspects that it was not capable of direct engineering evaluation. It remained again for Mr. Horton to develop, specifically, the hydraulics of overland flow, and to illustrate it with the meager data which he found available in 1935.[7] An evaluation of surface detention has now been found to be of extraordinary engineering importance in studies of rainfall-runoff relationships from small areas. As shown in detail in Part II, it is fundamental that at the end of a period of excess rainfall a part of the "supply" will be in the form of a layer of water in transit over the surface. So long as this persists on any part of the surface, infiltration will occur out of it at capacity rate, and the surface runoff will be less than the supply by the volume so extracted. The depth of surface detention will vary with slope, character of surface and cover, and with the rate of production of supply. For surfaces such as pasture or forest litter on flat slopes at the end of periods of high excess rainfall, surface detention will be very great; the time required to dispose of it will be considerable, and the abstraction through infiltration a significant quantity. For smooth surfaces, steep slopes, and small rates of excess rainfall, the quantity may be negligible.

The term "retention" is used herein to define that part of the supply which is abstracted permanently during the period of excess rainfall. It includes interception and depression storage. Its requirement must be satisfied out of the early precipitation; interception out of the first period of precipitation; and depression storage out of the first period of excess. The water quantities so abstracted will remain on the foliage or in depression storage at the end of the period.

For smooth, cultivated land, the value of retention appears to be on the order of 0.05 to 0.10. For contour cultivation it is considerably greater under good management. For good pasture it may be as high as 0.2, and for good forest litter up to 0.3. Abstractions in such amounts will occur during the early part of the storm. These quantities will be removed by evaporation and infiltration after the end of precipitation, or as to depression storage, after the end of excess rainfall. In large storms, if there are several hours of little or no precipitation, retention may be wholly or partly disposed of, and the requirements must again be filled during the subsequent part of the storm. In one long storm studied for a forested area, it appeared that retention actually exceeded one inch of rainfall. For compact storms, except where the cover is good grass or forest litter, the values of retention may be negligible.

In the procedure outlined herein, the foregoing factors should be recognized and applied in the following manner:

Characteristic values of interception and of depression storage may be determined from an analysis of the small watershed hydrographs. After excess rainfall has been computed for each time unit, values of interception and depression storage should be deducted from such excess in the time units where either interception or the filling of depression storage may obviously occur.

For small drainage areas where the infiltration pattern is set up in 10-min units and where it reflects precipitation intensity accurately, an allowance for infiltration out of surface detention must be determined in the manner illustrated in Part II. For large drainage basins where precipitation is set up in hourly mean values, and where no recognition is given to the rates which may occur within the hour, the resulting net rainfall computed will probably be less than the true value. Under these conditions, infiltration out of surface detention may be neglected and the two errors will be considered as compensating.

VI—Translation of Mass Surface Runoff to Hydrograph Form.—The final stage of this application involves the translation of the excess rainfall diagram into stream flow, generally through unit hydrographs of excess rainfall, or through surface detention and channel storage computations. It is assumed herein that, for most basins, net excess rainfall produced on the land represents surface runoff, and that this in general will be substantially equivalent to stream flow volume for a storm period and related rise of the hydrograph. A reduction will occur between surface runoff and stream flow where a part of the runoff is lost as seepage into stream bed or bank or on flood plains. An increase will occur where a part of the infiltered water returns to the stream system, during the rise of the hydrograph. There are exceptional conditions, as for some basins, where the return flow through the ground is so rapid as to constitute a considerable part of the flood flow. For such basins, infiltration capacity may be used to evaluate the hydrograph of surface runoff, and a separate procedure is developed to determine the hydrograph of ground water return flow. For many basins the latter is an insignificant part of the flood hydrograph and may be neglected.

PART II.—APPLICATION OF DESIGN METHODS

INTRODUCTION

It is intended in this part of the paper to accomplish two objectives:

(*a*) To permit a better visualization of the various factors and processes discussed in Part I by actually applying them to a small restricted area of conventional type, such as a developed city block; and

(*b*) To show the character of the runoff that will occur from such a conventional area, since the hydrograph will differ because of differences in certain controlling variables. After producing the actual synthetic hydrograph for

each combination of conditions, it is proposed to discuss the relation of the peak flow to the mean rainfall in terms of the accepted definition of the coefficient of runoff.

For the purpose of this demonstration, three precipitation periods have been chosen, having respective durations of 20, 40, and 60 min. The mean intensity for each of these durations is that taken from the rainfall curve shown in Fig. 5(*a*), which is substantially a 5-yr rainfall curve for St. Louis (see Table 1 for inlet areas corresponding to curves I to V). In the ordinary application of the rational method, precipitation intensity for specific duration periods is customarily considered as if it were uniform for the period. This is a condition that practically never occurs in nature. The probable occurrence of intensities for parts of the duration period has been investigated (see Fig. 2). For the purpose of this demonstration, the mean intensity for each period has been broken up into probable intensities and durations in approximate accord with the results of the analysis by Mr. Breihan.[3] For the 60-min precipitation period, these sub-intensities and duration units are shown on each of the diagrams, Figs. 5(*b*), 5(*c*), and 5(*d*). Mr. Breihan's investigation did not extend to the order in which these sub-intensity blocks might be expected to appear, and no other good investigation of this kind has been reported. The nearest approach to such a study is that described by D. I. Blumenstock,[9] but this relates only to variations in mean intensity, from hour to hour, within storms of considerable duration.

Experience has shown that each of the intensity patterns shown in Figs. 5(*b*), 5(*c*), and 5(*d*) may be expected to occur at some time, pattern 5(*b*) being the most common. The three patterns shown have been chosen arbitrarily for the purpose of this investigation and are referred to hereafter as the "advanced," "intermediate," and "delayed" patterns.

Mr. Breihan's investigations did not extend to a similar variation of intensities within precipitation periods of less than one hour. For the purpose of this investigation, the variations during the periods of 40 min and 20 min have been proportioned in a manner similar to that which was found for the one-hour period (see Figs. 6 and 7).

PHYSICAL CHARACTERISTICS OF THE AREA TO WHICH RAINFALL IS APPLIED

For the purpose of this investigation, Fig. 8 shows a conventional city block bisected by a paved alley. There are twelve 50-ft lots on each street frontage. The actual areas devoted to roofs, sidewalks, driveways, street and alley

pavements, and lawns are shown in detail in Fig. 8(*b*) and Table 2. The general conditions correspond rather closely to one of the city blocks heretofore gaged in St. Louis. Not only is the percentage of the area of each of these classes important (see Table 2), but the position of the area within the block significantly affects the character of its runoff hydrograph. Equally important are the surface slopes of each component part of the area. Figs. 5, 6, and 7 are based on overland flow slopes of 1% and alley gutter slopes of 0.5%.

3	Impervious	62.9	27.2	64.4	46.4	42.8

It is assumed herein that the sewers to be designed are separate storm sewers, that there is no storm sewer abutting the lot frontage, and that therefore all drainage is routed through either the street gutters or the alley pavement. Roof drainage is presumed to be collected in house gutter systems and carried through downspouts and short sewers to outlets through the curbing into the gutter. In this respect the conditions are different from those heretofore described for the St. Louis blocks gaged, where the sewers were of the combined type, and the roof drainage was connected directly to the sewers.

Routing roof water through the street gutters will increase, slightly, the time of its arrival at the collecting point manhole (manhole A, Fig. 8(a)) and give a slightly delayed runoff peak for the city block as a whole.

INFILTRATION CAPACITY

Fig. 5(a) shows a curve of infiltration capacities throughout the precipitation period. This curve is not intended to represent a specific condition accurately, but follows somewhat the curve of infiltration capacity under 2-in. rainfall rates, as computed from the small plots tested at Washington University in 1923 (see Fig. 3(b)). It may be characterized as representing, rather closely, the march of infiltration capacities that would exist for a turfed area; a soil condition consisting of about 4 in. of loam underlain with yellow clay, and a moisture condition that would exist in St. Louis during a midsummer period in which heavy rains occurred about twice a month, the last one approximately two weeks in advance of the conditions that this curve represents.

As far as is known, no sprinkling plot experiments have been made on well-developed city lawn grass. The nearest approach to such a situation, other than the Washington University tests, is in the runs made on the Anacostia Parkway, for which one graph has been shown (Fig. 3(a)). For that area, however, the soil is a plastic mud fill and not comparable to the ones referred to herein.

A preliminary study of rainfall-runoff relationships reported in 1934[10] indicates that both infiltration capacity and retention characteristics are higher for such lawns than for the sprinkling plots otherwise reported. This is undoubtedly due to the fact that such lawns are frequently mowed, are undisturbed by cultivation, and that it is possible, therefore, for extensive porosity to develop because of dead root growth and absence of compaction. Retention values are also increased because of the mat of grass-cutting litter that accumulates at the ground surface, and infiltration opportunity is extended for the same reason.

The calculations herein will involve somewhat lower infiltration capacities than may be expected under the same summer conditions on the city lawns, and somewhat less retention than will exist on such lawns; and therefore the resulting rates of runoff will be higher than would be expected for such conditions. This fact, however, does not affect the validity of the calculations with respect to the assumptions on which they are based.

In Fig. 5(a), the infiltration-capacity curve is shown in the position it would have held had it been actually derived from such a plot under a uniform 2-in. rainfall rate. For application to the precipitation patterns shown in Figs. 5(b), 5(c), and 5(d), the position of the curve has been adjusted slightly. For the purpose of this adjustment, it was assumed, the initial condition being the same for each diagram, the infiltration capacity would arrive at any specific rate when the mass infiltration was the same as that which preceded the occurrence of such a rate in Fig. 5(*a*). Specifically, in the adjusted positions, the 2-in. infiltration-capacity rate is so placed in time that the mass infiltration occurring prior to that time will be the same for each of the diagrams; and a similar adjustment was made with respect to other critical rate points on the curve.

---

[10] "Relation Between Rainfall and Run-Off from Small Urban Areas," by W. W. Horner and F. L. Flynt, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 140 (first published in *Proceedings*, Am. Soc. C. E., October, 1934).

For the rates of 40 min and 20 min duration (Figs. 6 and 7) the infiltration capacity was adjusted in a similar manner. It is recognized that present knowledge of the mechanics of infiltration is not such as to validate this adjustment procedure fully, but a study of the St. Louis infiltration-capacity curves appears to indicate that for any initial condition, the march of infiltration-capacity rates is closely correlated with mass infiltration. There is good evidence of a similar correlation at the Edwardsville station of the Soil Conservation Service.

PRECIPITATION, INFILTRATION CAPACITY, AND NET RAINFALL

The elemental surfaces shown on the city block fall into either the pervious or impervious class. The position, size of these surfaces, and the direction and length of overland flow are shown subsequently in Figs. 10(*b*) and 11(*b*).

For simplicity, it is assumed for the impervious surfaces that there is no permanent retention and no infiltration, although in an actual case a very small amount of each may exist. Therefore, net rainfall is equal to the precipitation, and the rate of production of net rainfall or "supply" (hereafter given a symbol σ) is represented by a precipitation intensity diagram.

For the pervious surfaces, it is assumed in all cases that the permanent retention is 0.1 in. It appears to be reasonably representative of the turfed areas that have been studied under sprinkling plot experiments. One half of this retention, or 0.05 in., is assumed to be of the character of interception, and is taken out of the first 0.05 in. of rainfall that occurs. The other 0.05 in. is treated as depression storage and is taken out as the first 0.05 in. of net rainfall after infiltration capacity drops below the precipitation rate. As stated, these values are undoubtedly somewhat lower than will actually exist on well-developed city lawns.

With this allowance for retention, the rate of production of net rainfall or "supply" is determined by subtracting the infiltration capacity rates from the precipitation intensity rates, and the result is shown in Figs. 5, 6, and 7; and, as so shown, represents the diagram of net rainfall or rate of production of surface runoff for the pervious area.

These two "supply" diagrams (that is, the precipitation intensity diagram as to impervious surfaces and the net rainfall diagram as to pervious surfaces) determine the mass values of surface runoff that are thereafter unchanged (except for a small amount of infiltration during the recession period), and appear in the same values under the varying rate diagrams for overland flow for each particular surface, for inflow into the street and alley gutters and for the final runoff hydrograph for the city block as a whole, at manhole *A* (Fig. 8(*a*)).

OVERLAND FLOW AND SURFACE DETENTION

The characteristics of overland flow have been the subject of extensive investigation through the analysis of rainfall plots. It has been extensively discussed by Mr. Horton.[7, 11] The field investigations have shown that overland flow in thin sheets may be entirely turbulent or partly turbulent and partly laminar. For smooth surfaces, it appears that fully turbulent flow will be developed normally, and that the Manning formula is applicable. For subdivided flow through grass, most of the experimental data indicate that the flow is laminar to some extent and may be reasonably represented by a condition of 75% turbulent flow, in which case the profile of overland flow may be assumed to be parabolic and the flow to take place in accordance with the relation,

$$Q = k\,\delta^2 \qquad (1)$$

in which: δ is the depth of flow at any point; k is a constant; and Q is the rate of flow. Since the profile of the water surface is parabolic, in this case, the mean depth of surface detention may be taken as two thirds of the depth at the outflow margin of any strip, and the rate of outflow may be expressed either in terms of mean depth or of outflow depth. For the purpose of this demonstration, it is assumed that the flow from paved impervious surfaces will take place in accordance with the Manning formula, using an n of 0.015, and may be represented by the equation

$$V = 18.9\,\delta^{0.67}\,S^{0.5} \qquad (2a)$$

in which V is in feet per second and δ is in inches. It is assumed that the flow over turfed surfaces will be 75% turbulent. Coefficients have been adopted from a study of several sets of experimental data, and the flow formula used is

$$V = 0.96\,\delta\,S^{0.5} \qquad (2b)$$

The values of n derived from experimental studies of turfed plots and used in Eq. 2*b* are not of the same order as the Manning n, because the condition is actually one of subdivided flow. For evaluation of overland flow through turf, it seems advisable to avoid the use of values comparable to the Manning n and to discuss rather the velocity coefficients in Eq. 2*b*. The Anacostia plot (Fig. 3(*a*)) gives a coefficient of slightly more than 0.6. The aforementioned value of 0.96 was derived by the writers from experiments reported in 1938.[12] Unpublished values for flows 1 to 2 in. deep through Bermuda grass[13] indicate that these can be expressed by a coefficient of about 1.2, although the flow was turbulent. In general, these values over a considerable range of turf conditions seem to have less variation than the n-values for natural stream channels.

---

[11] *Transactions*, Am. Geophysical Union, 1939, p. 693.

[12] Unpublished manuscript of the SCS entitled "Results of Studies Involving the Application of Rainfall at Uniform Rates to Control Plot Conditions," by C. M. Woodruff, D. D. Smith, and Darnell M. Whitt, June, 1938.

[13] "Some Experiments on Shallow Flows over Grass Slope," by W. O. Ree, Spartansburg Lab., SCS, *Transactions*, Am. Geophysical Union, 1939, Pt. IV, p. 653.

If any specific project is undertaken for the development of truly representative hydrographs of flow involving the turf on city lawns, the value of the coefficient in Eq. 2*b* should be given some further study. For the reasons heretofore discussed, it appears that on well-developed city lawns, this coefficient may be as low as that found for the Anacostia Parkway—that is, on the order of 0.6. This assumption is borne out in part from an examination of an actual hydrograph for one of the city blocks studied previously,[10] where the delayed peak and the considerable bulk of flow occurring after the end of rainfall indicate in part relatively low velocities of overland flow.

On the basis of the flow-depth relationships of the foregoing type, Mr. Horton has developed, for 75% turbulent flow, the equations for the rising side of the hydrograph, and for the depth of detention corresponding to any rate of flow.[14] These equations, when developed from Eqs. 2, become:

For turf—

$$q_s = \sigma \tanh^2 \left[\frac{1.5 \sqrt{3{,}520}\; \sigma^{0.5}\; S^{0.25}\, t}{60\; l^{0.5}} \right] \ldots\ldots\ldots\ldots (3a)$$

and

$$\delta = \frac{l^{0.5}\, \sigma^{0.5}}{S^{0.25} \sqrt{3{,}520}} \tanh \left[\frac{1.5 \sqrt{3{,}520}\; \sigma^{0.5}\, S^{0.25}\, t}{60\; l^{0.5}} \right] \ldots\ldots\ldots (3b)$$

Figs. 9(*b*) and 9(*c*) show families of curves for runoff across turf strips for different slopes and lengths.

For pavement, the writers have developed the following relationships:

$$q = \sigma \tanh^{1.67} \left[\frac{1.60\; (1{,}020)^{0.60}\, S^{0.30}\, \sigma^{0.60}\, t}{n^{0.60}\, l^{0.60}\; 60} \right] \ldots\ldots\ldots\ldots (4a)$$

and

$$\delta = \frac{\sigma^{0.60}\, n^{0.60}\, l^{0.60}}{(1{,}020)^{0.60}\, S^{0.30}} \tanh \left[\frac{1.60\; (1{,}020)^{0.60}\, S^{0.30}\, \sigma^{0.60}\, t}{n^{0.60}\, l^{0.60}\; 60} \right] \ldots\ldots (4b)$$

In Eqs. 4, q is expressed in inches per hour, σ = the rate of supply of excess rainfall in inches per hour, S = the absolute slope, l = the length of overland flow in feet, t = time in minutes, n = the coefficient of roughness, and δ = the depth of detention, in inches, at the outflow margin at any time t. The mean depth of detention is for turf $\frac{2}{3}\,\delta$ and for pavement approximately $\frac{5}{8}\,\delta$.

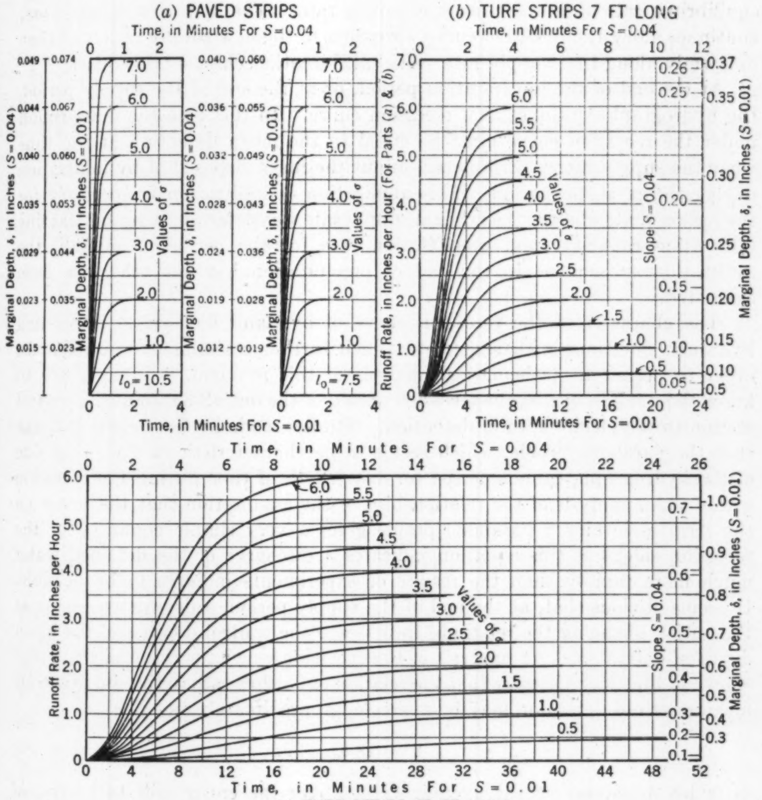
For any specific area of surface, such as those shown in Fig. 8(*a*), S, l, and n are inserted and Eqs. 4 then show the relation between the rate of overland flow or the marginal depth of overland flow and the rate of supply at any time t. For each condition of flow, Eqs. 4 have been graphed for overland flow over 10.5-ft and 7.5-ft lengths of pavement, for various rates of supply. (See Fig. 9(*a*).)

In determining the hydrograph of overland flow, the q equations, Eqs. 3*a* and 4*a*, are applied to the rate of supply shown on the diagram, as for example, in Fig. 5(*a*). Where the rate of supply is varying, the procedure is simplified by reducing the rates to uniform rates for short periods. Where the rate of supply is uniform for a considerable time, the rising side of the hydrograph is that represented by Eqs. 3*a* and 4*a* for any single rate. If the uniform rate of supply continues for a considerable time, equilibrium flow is established and the rate of overland runoff becomes equal to the rate of supply.

---

[14] "The Interpretation and Application of Runoff Plat Experiments," by Robert E. Horton, *Proceedings*, Soils Science Soc. of America, Vol. 3, 1938.

If the supply rate increases either before or after equilibrium flow has been established, the rising side of the hydrograph is continued as follows: The surface detention at a time when the supply rate increases is related to the value of Q by Eq. 1. This same value of detention would have been produced under the second supply rate at a different time, and the Q corresponding to such δ at that time has the same value as the Q resulting from the first supply rate. Accordingly, it is possible to join two different curves representative of the rising side of the hydrograph for different supply rates. For example, in Fig. 9(*c*), if the initial supply rate was 1.5 in. per hr and it lasted for 16 min,



(*a*) PAVED STRIPS

(*b*) TURF STRIPS 7 FT LONG

(*c*) TURF STRIPS 65 FT LONG

FIG. 9.—RUNOFF RATES, OVERLAND FLOW

the rate of runoff at that time would be 1 in. per hr. If at that time the supply rate changed to 2.5 in. per hr, the hydrograph can be continued by using the curve for the 2.5-in. supply rate at the point of equal flow which, for that curve, is found at 8 min. The rising side of the hydrograph will then develop along this curve until the supply rate is again changed.

When the supply rate is reduced from one value to another, the hydrograph takes the form of a recession curve, the rate at the lower end of which is the equilibrium rate of flow for the new supply rate. The hydrograph, therefore, continues along the recession curve, dropping to the new supply rate, and then uniformly along that supply rate value until another change takes place.

At the end of the precipitation period, or at the end of the supply period, the hydrograph continues as a recession curve. In this case the mass runoff under the recession curve must be equal to the mean detention at the time when the supply rate is terminated, minus the mass disposed of by infiltration during the recession period. This application of infiltration is necessary for the reason that, whereas the original supply rate was determined by subtracting infiltration capacity from precipitation rate for the period of rainfall, the infiltration subsequent to the end of precipitation has not otherwise been evaluated.

The character of the recession curve of overland flow raises interesting hydraulic questions with respect to which further research is desirable. In order to permit a mathematical analysis of this problem, it is necessary to know the relation during the recession period of the outfall depth at the control section to the mean depth of detention. Studies made by the writers indicate that the parabolic profile, which seems to be characteristic of the rising side of the hydrograph, cannot persist for any length of time during the recession period. An analysis of the relationships of the assumption that the water on the strip maintains a parabolic profile gives a very simple equation for the recession side, but this equation indicates a discharge of the detained water much more rapidly than the results of experiments indicate to be possible. It seems obvious that, at the end of the supply period, a drawdown occurs at the outlet, changing the relationship between the control depth and the mean depth of detention. An analysis of the recession curve for the Anacostia plot shown in Fig. 3(*a*) indicates that the relation of outflow rate to the simultaneous mean depth of detention may be expressed approximately as

$$q = 18\,\delta_a \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (5)$$

in which δ_a represents the average depth, over the entire tributary area, of the residual detention at that time. Further study of a large number of such recession curves may give a better indication of how the water surface profile is modified during this period. For the purpose of the demonstration of this paper, the recession curves have been adjusted to conform generally to those of experimental plots that have been examined.[15]

The effect of this procedure in transforming the supply rate shown in Fig. 5(*a*) to a hydrograph of surface runoff, for each of the elemental areas

[a] Turf. [b] Pavement. [c] Roofs.

shown in Table 3, is illustrated in detail in Figs. 10 to 14 which follow. In all of these computations, the runoff rates are maintained in inches per hour.

The rainfall chosen to illustrate the application of this method is the simple one presented in Fig. 5(*a*). This rainfall is reproduced in Fig. 10(*a*), showing the respective outflow graphs for each of the elemental areas draining to the street. It is noticeable that for the smoothly paved areas equilibrium flow is quickly established, and the outflow graph departs comparatively little from the precipitation or "supply" diagram. The hydrographs for the turfed areas reflect both the effect of infiltration and surface detention. It will be noted that runoff becomes perceptible at about 18 min, which is approximately the beginning of the supply rate diagram as shown in Fig. 5(*a*). The difference between the hydrographs for areas *A*, *B*, and *C* reflects the difference in the length of overland flow, all of them having the same supply rate and the same surface slope, for this illustration, of 1%. The effect of the longer overland flow for unit *A* is also apparent in the increased depth of surface detention which results in the greater mass under the recession curve *A*.

In Table 3(*a*), each of these unit areas is shown in its actual acreage and also as a percentage of the area of the lot draining to the street.

In Fig. 10(*b*), the ordinates of the hydrographs in Fig. 10(*a*) have been multiplied by their respective areal percentages, and therefore appear in terms of inches per hour for the entire tributary area shown on the small plat in

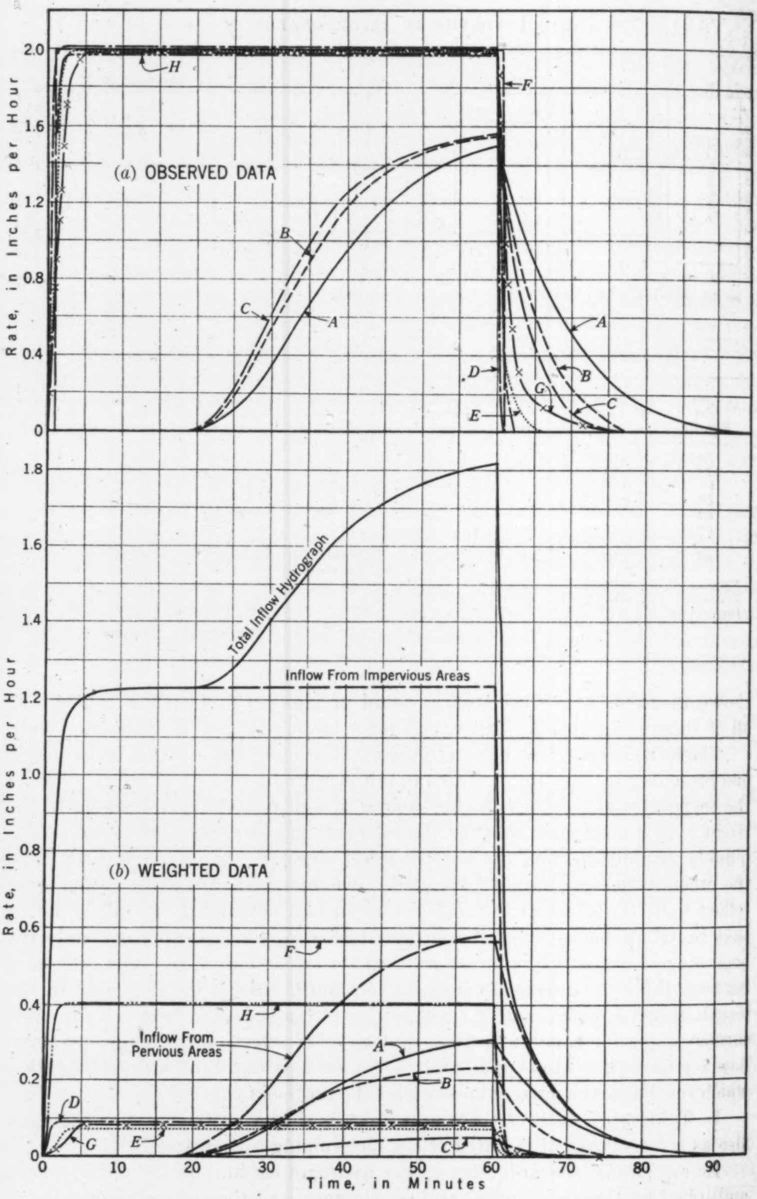

FIG. 10.—HYDROGRAPHS OF FLOW FROM A TYPICAL LOT TO A STREET GUTTER (RAIN, 2 IN. PER HR FOR 60 MIN)

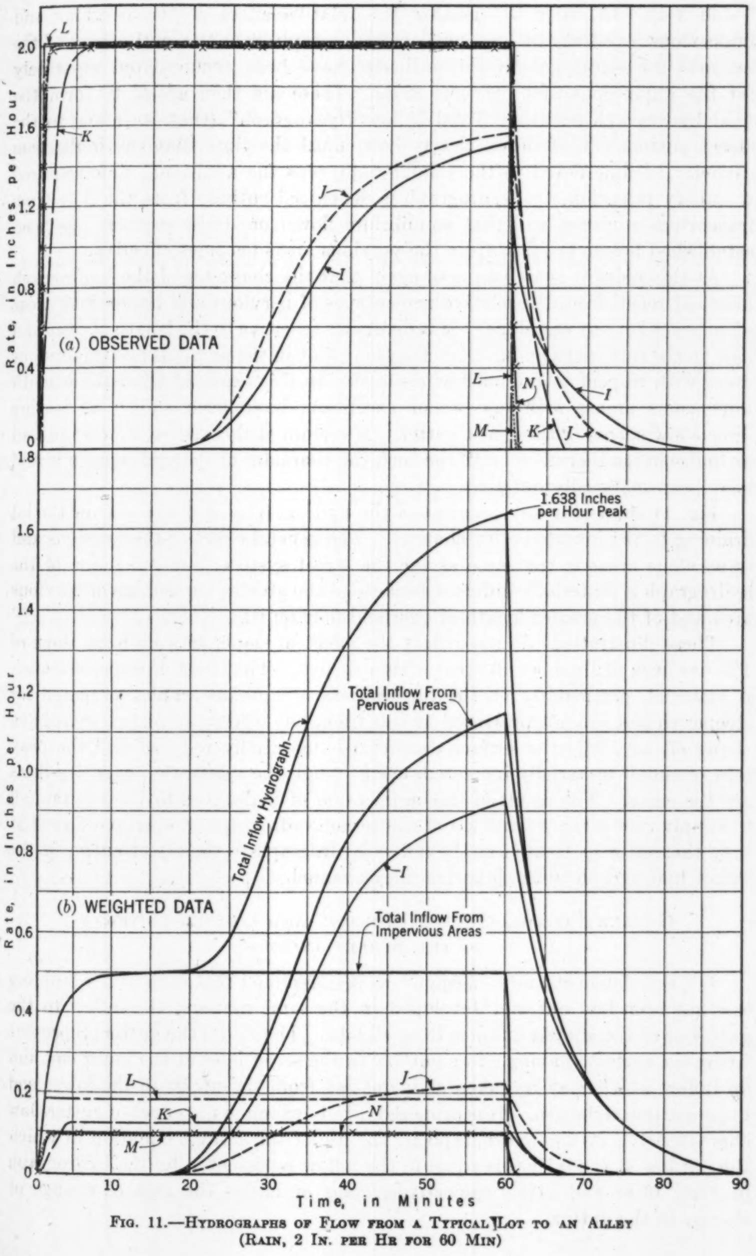

FIG. 11.—HYDROGRAPHS OF FLOW FROM A TYPICAL LOT TO AN ALLEY (RAIN, 2 IN. PER HR FOR 60 MIN)

Table 3(*a*). In order to visualize the relative effect of the pervious and impervious areas on the final outflow hydrograph from this entire part of the lot into the street gutter, the ordinates have been accumulated separately for the impervious and pervious units. These are then added to form the final hydrograph entitled "Total Inflow Hydrograph" (that is, inflow to the street gutter). This shows clearly how, until the time that the infiltration capacity became equal to the rainfall rate, plus the additional time required to satisfy retention, the hydrograph is developed entirely from the flow from impervious surfaces, and that equilibrium flow from these surfaces has been established before the flow from the pervious areas becomes effective.

At this point it is well to note again that the character of the hydrograph does not result from the relative percentages of pervious and impervious areas alone, even for any one slope. It is distinctly sensitive to the length of overland flow on the turf strips and to the relative position of the pervious and impervious areas with respect to the outflow channel. In this example all of the smooth impervious areas, with one minor exception, have been shown as having direct-flow access to the street gutter. If certain of these areas were so placed as to discharge their flow on to the turf, the character of the hydrograph would have been materially different.

Fig. 11 shows the development of the hydrographs from the rear of the lot draining to the inverted alley channel. The general effect of the pervious and impervious areas is the same as for the street system, but the shape of the hydrograph is materially different because of the greater percentage of pervious area and of the greater length of overland flow on it.

These illustrations do not reflect the effect of slope, as a uniform slope of 1% has been utilized for all areas within the lot. The effect of slope, however, is material, particularly on the turfed areas. Separate graphs, prepared for steeper slopes, are not presented at this time, but where the turfed areas have slopes of, say, 4%, the surface detention is materially reduced and the peak rate of runoff materially increased, even though the infiltration capacity rates are the same. The result of this application of hydraulics to the net rainfall or supply rate is the production of the actual hydrograph of overland flow that may thereafter be treated as the inflow hydrograph to the street gutter or the inflow hydrograph to the inverted alley channel.

GUTTER INFLOW, GUTTER STORAGE, AND GUTTER OUTFLOW TO THE STREET INLET

For this demonstration, inasmuch as it is assumed that each of the building lots has been laid out and developed in the same manner, the inflow to the gutter or to the alley is uniform from all lots. Therefore, the gutters represent hydraulic systems having a free outflow to the sewer inlet at the lower end and an inflow which may be taken as increasing from the upper to the lower end in proportion to length. It is proposed here to examine the effect of gutter-flow characteristics on the hydrograph by the use of the storage equation in which the outflow at the inlet Q is equal to the inflow represented by the hydrograph in Figs. 10(*b*) and 11(*b*), respectively, plus or minus the rate of change of storage in the gutter.

To permit this application to be made, it is necessary to develop, for any condition of equilibrium flow, the relation of the storage volume in the gutter to the discharge Q at the inlet. This storage volume is readily determinable when the character of the water surface profile is known. In this case, the relation between rate of flow to length of flow along the gutter is a linear one, in which

$$\frac{Q_x}{x} = \frac{Q_l}{l} \qquad \text{(6)}$$

being the total length of the gutter, and x the distance along the gutter measured from the upper end. For the alley-channel gutter, the width of the water surface is great compared to the depth, and the hydraulic radius may be closely approximated as being equal to the mean depth.

In ordinary municipal practice, it has been the custom to assume that the water surface is parallel to the flow-line gradient, in which case the depth h_x at any point x becomes a direct exponential function of the rate of flow Q_x at that point. For the conditions: $A = 15\,h^2$; $v = \frac{1.486}{0.015} R^{0.67} S^{0.5}$; $R = \frac{h}{2}$; and $v = 62.4\,h^{0.67}\,S^{0.5}$

$$Q = A\,v = 936.1\,h^{2.67}\,S^{0.50} \qquad \text{(7a)}$$

and, assuming a gutter 600 ft long,

$$V = 5{,}142.9\,h^2 \qquad \text{(7b)}$$

For this condition of flow, in the alley gutter shown in Fig. 12(*b*), the equation between h_x and Q, the outfall discharge becomes

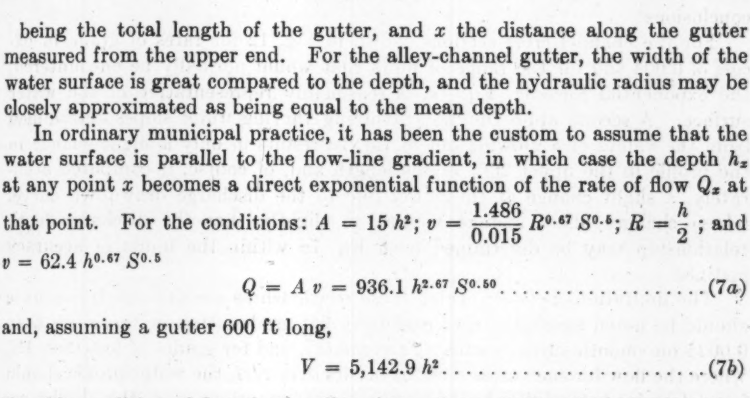

FIG. 12.—HYDRAULIC CHARACTERISTICS

$$Q = \frac{936\,l}{x} S^{0.5}\,h_x^{2.67} \qquad \text{(8)}$$

The assumption involved in Eq. 7*a*, of course, is physically inconsistent, as the values of h cannot vary along the gutter without producing varying values of the water surface slope i.

In connection with this demonstration, considerable study was made with respect to the character of the genuine water surface profile for the alley gutter. It was found that a rigid analysis of this hydraulic problem is quite involved, and that the matter could be approached best by successive approximations. The water surface profile has been investigated in this manner with the following conclusions:

For the channel cross sections shown in Fig. 12 for rates of grade in excess of 0.004 and for the range of flows that would normally be encountered, the exponential formula, Eq. 7*a*, is reasonably representative of the water surface. A second approximation involving varying water slopes determined from the values of h growing out of Eq. 7*a* results in only a slight change in the profile in the upper 20% of the length and, of course, if computed accurately, a slight change at the outlet due to the discharge drawdown curve. These changes affect storage volume so slightly that the discharge-depth relationship may be determined from Eq. 7*a* within the limits of accuracy justified.

The limitations between which these relationships are sufficiently accurate should be noted carefully. For extremely flat grades (that is, those less than 0.0025 on smooth surfaces such as pavement), and for grades of less than 1% where the flow for such cross sections occurs over turf, the water profile should be determined carefully by successive approximations and the discharge-storage equation developed by summation. This has been found to be particularly important in studies made for the drainage of the National Airport at Washington, D. C., where the channel flow is entirely through flat turfed gutters. Under these conditions, storage volume reaches large quantitative values with respect to discharge Q, must be rather accurately determined, and affects, importantly, the relation between channel inflow and outflow.

The relationship between storage volume and depth at the outlet has been evaluated and is shown for the alley on the control graph, Fig. 12(*b*). It can also be expressed directly as a relation between discharge rate and storage volume.

This can be done by eliminating h between Eqs. 7*a* and 7*b* for the alley, which results in the following relationship:

$$V = k\,Q^{0.75} \qquad \text{(9a)}$$

n which V is in cubic feet; and Q in inches per hour for tributary area A in acres and, for this block,

$$k = \frac{60\,l}{7}\left(\frac{A}{936\,S^{0.5}}\right)^{0.75} \qquad \text{(9b)}$$

With Q expressed in cubic feet per second, Eq. 9*b* becomes

$$k = \frac{60\,l}{7}\left(\frac{1}{936\,S^{0.5}}\right)^{0.75} \qquad \text{(9c)}$$

This is the value of k used in Eqs. 12. For a short finite Δt in which the hydrograph may be taken as a straight line, the insertion of these values in the storage equation, with inflow I in cubic feet per second, gives

$$60\,I\,\Delta t - \frac{Q_1 + Q_2}{2}\,60\,\Delta t - (k\,Q_2^{0.75} - k\,Q_1^{0.75}) = 0 \quad \text{(10)}$$

Rearranging the terms, this can be expressed as

$$fQ_2 = I + fQ_1 \quad \text{(11)}$$

in which (expressing I, Q_1 and Q_2 in inches per hour)

$$fQ_2 = \frac{2\,k\,Q_2^{0.75}\,A^{-1/4} + 60\,Q_2\,\Delta t}{120\,\Delta t} \quad \text{(12a)}$$

and

$$fQ_1 = \frac{2\,k\,Q_1^{0.75}\,A^{-1/4} - 60\,Q_1\,\Delta t}{120\,\Delta t} \quad \text{(12b)}$$

This relationship is shown graphically in Fig. 13. Similar diagrams were prepared for the street gutter and were used to translate the gutter inflow hydrograph to the gutter outflow hydrograph. Because of the character of the street gutter cross sections, the equations are quite involved, and the work was done graphically.

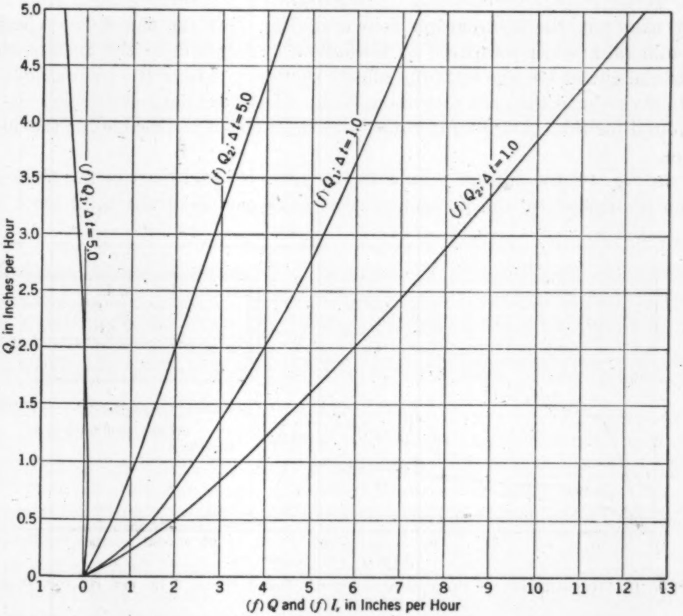

FIG. 13.—GRAPHS FOR THE SOLUTION OF THE STORAGE EQUATION FOR THE ALLEY

In this application, the value of I is the mean value for the period Δt; Q_1 is the value at the beginning of Δt; and Q_2 is the value at the end of period Δt in min; A is in acres. The graph in Fig. 13 has been prepared by inserting the value of k representative of the total tributary area to the alley for a length of 600 ft, and a slope of 0.005. The method of determining Q_2 from Q_1 is shown in an example by the dotted lines in this diagram.

For the purpose of this application, the inflow hydrographs of the type shown in Fig. 11(*b*) were modified by evaluating the rate of change of storage and adjusting the ordinates accordingly. The resulting outflow graph to the inlet from the alley channel is shown in Fig. 5(*a*).

It will be noted that for this case the storage volume is so small with respect to the mass of the flow quantity that the channel storage has no effect on the peak rate. However, it does modify the earlier part of the hydrograph somewhat. The earlier part of the hydrograph is important in translating these values to flow at a critical point on the sewer system, and therefore this modification also becomes important to the ultimate peak flow in the sewer.

The effect of gutter channel storage for the shorter and more intense rains is not apparent from the graphs. Actually, however, the reducing value of this gutter storage becomes highly important for the rains of 20-min duration. For example, the hydrograph shown in Fig. 7(*d*) for the delayed-pattern, 20-min rain, when compared to the inflow hydrograph to the gutters, shows that the gutter storage not only affects the rising side of the hydrograph, but actually reduces the peak rate about 30%. A similar but less drastic reduction is found for the other 20-min rains, and the effect is noticeable for the 40-min rains.

In Fig. 14, the outflow graphs to the inlets for each part of the block have been multiplied by the percentage that each part is of the total block area, and therefore transformed to inches per hour for the block as a whole (see Table 1 for areas). It has been assumed that the inlets are discharging into a sewer on the cross street; for this purpose the velocity in the sewer is taken as 5 ft per sec, the time of flow between the inlet connections has been evaluated, the hydrographs have been offset accordingly, and the ordinates have been

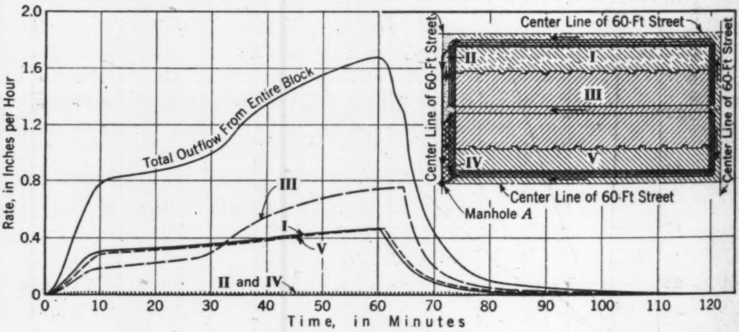

FIG. 14.—HYDROGRAPHS OF FLOW FROM A TYPICAL BLOCK (RAIN, 2 IN. PER HR FOR 60 MIN)

summed up to produce the total outflow graph from the entire block. (In Fig. 14, curves I, II, III, and IV are the weighted hydrographs of flow into inlets from areas bearing the same numbers.)

This graph, and the companion graphs in Figs. 5, 6, and 7, can be accepted as representing, rather accurately, the manner in which the flood flow from this block will occur at the concentrating manhole *A*. The flow so represented may be accepted as that which would result from the conditions assumed. Among these conditions, the character of the infiltration capacity curve and the amount of retention are important. As has been previously discussed, such graphs, if they are to be used quantitatively in sewer design, should be based on infiltration capacities and on retention values that have been developed out of actual flow gagings of such city lots. Undoubtedly the infiltration capacity for the turf on such lots and the characteristic retention on such turf will be found to be higher than those determined from the analysis of sprinkling plats. In this connection, the writers have made a quick preliminary review of the results of the gagings from station *B* (city block 4841 in St. Louis).[10] The development of this block as to character of surface cover and as to slopes is rather similar to the assumed city block outlined in Fig. 8(*a*). The principal difference is that the actual St. Louis block is nearly twice as long as that shown in Fig. 8(*a*). An analysis of the actual losses that occurred from the 70% pervious area in city block 4841 for a number of rains shows the results presented in Table 4. In this form, the values of losses have no specific significance. However, they can be broken down by analysis, between retention and total infiltration. The amount of infiltration, by comparison with the precipitation diagram, can be checked against infiltration opportunity. In this way, not only can mean infiltration capacity be determined, but by analogy to sprinkling plot results, an approximation can be made of the trend of infiltration capacity curve.

TABLE 4.—CITY BLOCK 4841, ST. LOUIS, MO.; 70% PERVIOUS

Date	Duration of rain, in min	Precipitation, in inches	Infiltration plus retention, in inches	Peak rate of runoff from area tributary to alley, in inches per hr	Date	Duration of rain, in min	Precipitation, in inches	Infiltration plus retention, in inches	Peak rate of runoff from area tributary to alley, in inches per hr
8- 2-15	60+	1.29	1.22	1.45	10-27-18	15	0.63	0.42	1.00
5-28-16	30	0.64	0.24	1.50	4-19-20	60+	1.30	0.68	1.95
6- 2-16	20	0.91	0.55	1.55	8-27-21	40	1.77	1.27	1.60
8-11-16	20	0.77	0.60	1.55	8- 8-23	50	3.51	3.00	2.45
8-12-16	60+	1.14	0.65	1.35	6-23-24	50	1.36	0.92	1.50
9- 7-16	10	0.78	0.54	1.65	8-24-24	15	1.13	0.89	1.80

Of course, the peak rate of block flow such as the 1.68 in. per hr of Fig. 5(*a*) for manhole *A* is not the critical rate for which the sewer would be designed at the outlet of this block. The importance of this hydrograph relates to the design of the sewer at some point where the so-called "critical time" is approximately 60 min. At that point on the sewer, if all the blocks in the drainage basin had the same typical development as shown herein, the hydrograph of discharge may be determined by offsetting the hydrographs from the various blocks, adding the ordinates, and making some further modification in the shape of the hydrograph that would result from the translation of the flood wave under this condition. This process has been applied to each of the hydrographs, the routing being traced through a typical rectangular sewer system.

The outflow graph at manhole *A*, representing the hydrograph of outflow from the entire city block, has been calculated for each of the three duration periods and each of the four rain patterns, and the full hydrographs are shown in Figs. 5, 6, and 7. In these figures there has also been indicated a value of the net rainfall or supply graph for the block as a whole. This is a weighting of the supply graphs for the pervious and impervious area with respect to the proportionate amount of these two types in the block.

For ease in inspection there has also been noted on each of the graphs the character of the hydrograph as it would appear after routing to the flow time point on the sewer system equivalent to the duration represented by the particular rain. By inspection, therefore, it is possible to note the following:

Comparison between the precipitation diagram and the weighted supply line shows the effect of the infiltration and the permanent retention that was introduced into the computations. A comparison between the supply line and the hydrograph at manhole *A* (Fig. 14) shows the combined effect of surface detention during overland flow and of gutter storage. The comparison between the hydrograph at manhole *A* and the hydrograph at the design point shows the equalizing effect resulting from the non-synchronous concentration of the flow from the various city blocks at this point. These last hydrographs, as to their peak values, are representative of the quantities such as have heretofore been commonly used in sewer design under the rational method. For those

[a] Rectangular drainage network (see text). [b] Advanced, intermediate, and delayed, respectively.

who are accustomed to thinking in terms of the coefficient of runoff, these peak rates may be compared with the mean precipitation intensity for the original duration period. These particular peak rates, of course, result from the particular network routing system used. This rectangular system with equally spaced branches, and with the flow time in the branch equal to the flow time in the main, is only one of a number of patterns that might have been applied. Higher peak rates would have resulted if the network system had been chosen of the sector type with the branches converging toward the time design point.

In order to give a general perspective view of the results of the calculations here presented, Table 5 has been prepared. All of the values given in this table are expressed in inches per hour, or the approximate equivalent cubic feet per second per acre, except the mass values of supply Q and infiltration F, which are in inches in depth distributed over the entire tributary area. It should be noted again that, quantitatively, the values are responsive directly to the rainfall patterns and to the infiltration capacity values used, and as to the latter, result in runoff rates greater than would be expected with the frequency involved. The values given for peak flow at the various time-design points reflect the particular network sewer pattern previously described and would be materially different for a different type of collecting system. However, they all have been derived on the same basic assumption and through the same application of hydraulics, and therefore are definitely comparable.

Summary and Conclusions

Conventional Urban Areas.—The conception of a uniform rainfall rate for a specific duration period is an unsatisfactory basis with which to compare runoff rates. In the opinion of the writers a fully rational basis of design for urban storm drainage involves the following steps:

(*a*) A study of rainfall intensity distribution and of the sequence of intensities within certain arbitrary duration periods, such as those chosen in this paper.

(*b*) For a particular area, some further research is needed with respect to infiltration capacity and overland flow for the type of turf normally utilized for city lawns.

(*c*) With the necessary basic data, it is entirely practicable and not an unreasonably involved or expensive procedure to develop, through hydraulic processes, the type of hydrographs shown in this paper.

(*d*) The rates so determined, on the basis of the conditions for which they are derived, should be subjected to a further frequency investigation, and from these studies a series of design curves might be prepared that would give the peak rate of runoff expected from each of the typical blocks, for specific slope conditions, and at any particular frequency.

(*e*) No attempt should be made to reduce these basic design values to generally applicable flow rates at any "time point," but in the design of any particular sewer system they would form the basis of flow routing through the particular drainage network.

(*f*) The procedure in steps (*a*) to (*e*) is subject to organization and tabulation in a manner similar to that under which the rational method has been commonly applied. It removes, entirely, the completely irrational coefficient of runoff; it involves a further study and revision of the criteria of critical time; it implies that the critical runoff rates at the sewer inlets will be routed through the sewer network in such a manner that the maximum rate of flow which can occur at any design point will have been determined; its application initially will require the extensive preparation of essential basic data, and extensive studies as to the physical characteristics of typical city blocks. Its application in general, after basic hydrographs of determined frequency have been prepared, will be little more difficult than the methods now used.

PART III.—CONCLUSION

The demonstration presented herein for small conventional areas shows, in principle and outline, the manner in which hydraulic methods may be applied to the organization of basic data and the derivation of secondary data essential to the computation of flood flow rates. The writers believe that basic hydrologic data are now becoming available, of a quality and in an extent that justify the more detailed type of hydrologic analysis set out, and that hereafter the basis of design of important hydraulic structures may be developed in a more logical and dependable manner than has heretofore been considered feasible. That the computations involved will be tedious in some cases is recognized; but they need be no more extensive, nor complex, than the technical computations commonly underlying the design of an important bridge.

The procedure outlined in detail for small areas of conventional type has been applied with some modifications, but upon the same basic principles, to larger drainage basins and to natural channels.

When applied to larger areas, all matters may obviously be on a somewhat different scale, and some phases of the computation are properly of a more approximate character. However, even as to such large areas:

(*a*) Precipitation patterns can be prepared for each important sub-basin, preferably in units not exceeding 1,000 sq miles;

(*b*) Infiltration capacity values reasonably well related to actual soil and cover conditions can be accumulated separately for each sub-basin, and can be matched with the pertinent precipitation pattern in a logical manner;

(*c*) From such a combination, the rate of production of surface runoff from each sub-basin will be developed in the order and manner in which it would actually occur;

(*d*) The diagram of surface runoff can then be translated into the hydrograph of stream flow at any particular point in each sub-basin through the unit graph or a proper evaluation of surface detention and channel storage. The hydrographs for the sub-basins can then be synchronized and combined for the main stream. This application unquestionably requires more detailed physical data as to stream channels and valley storage areas, and involves a material increase in the cost of the design phase of the engineering of hydraulic

UNIVERSITY OF MICHIGAN LIBRARIES

structures; but it permits a marked reduction in the factors of ignorance that need to be applied thereto.

This procedure is restricted to the determination of flood flow from surface runoff. For many basins, ground water or base flow during the rise of the hydrograph will have a small value and may be neglected. For some conditions it may be large and may add materially to flood flow. Any detailed discussion of this question is beyond the scope of this paper.

DISCUSSION

L. L. HARROLD,[16] ASSOC. M. AM. SOC. C. E.—To obtain data for the design of urban storm sewers, the authors have undertaken to utilize both hydrologic and physical data to develop "in place" surface runoff, and then have shown how the "in place" surface runoff can be routed through gutter systems by established hydraulic principles.

The paper implies that these hypotheses can be adapted to natural watersheds. It appears to the writer that there is no reason why they are not applicable as long as the natural watersheds produce only surface runoff. Many drainage areas are of this class, whereas the hydrology of other areas is complicated by the presence of ground-water flow and subsurface storm flow. By "subsurface storm flow" is meant that water which filters through the soil surface, forming temporary perched water, and flows laterally and appears at the ground surface lower down the slope. This subsurface storm flow, which joins the stream while surface flow is still in the drainage system, has not the characteristic of true ground-water flow because of its quick return to the surface and its short duration.

Even though the application of these hypotheses may be limited to those drainages where surface runoff constitutes the entire storm flow, there is still a wide field of possible use.

For example, if the hydraulic engineer in charge of designing the size of highway bridge openings knows the hydrologic and physical data of the natural drainage above the site (as did the authors for the urban block), the corresponding hydraulic design data can be derived. To the extent that certain watershed changes, such as the introduction of different land use practices or the construction of conservation structures, increase or decrease the surface retention and infiltration capacity of the basin, they will affect the rates and amounts of runoff from the area. The hypotheses presented furnish a vehicle for computing this effect at various points in the drainage system.

The problem can be related more closely to the example of the urban block described by the authors. If the 46.4% area of impervious surface were increased to 70%, could the sewer system handle the runoff? By applying the method to obtain the revised hydraulic design data, the engineer could tell the zoning commission that, if the district is to become "commercial," additional impervious surfaces are possible, and a certain sum of money will be necessary to enlarge the storm sewer system.

The writer has not overlooked the fact that these hypotheses must be checked in the field. It soon will be possible to perform the check over widespread areas. The Geological Survey, U. S. Department of the Interior, is collecting topographic and runoff data. The Weather Bureau, U. S. Department of Agriculture, is collecting rainfall data. The Department of Agriculture also is engaged in obtaining data on soils, land use, and infiltration. Several federal agencies are engaged in computing infiltration-capacity values for large areas by correcting the runoff record for channel storage and by relating the resulting direct runoff value to the precipitation data. At this point the writer would like to emphasize the importance of using the precipitation data separately for each gage, rather than combining the records for several gages. This is especially important when some of the rain falls at rates less than the infiltration capacity. When the rainfall rate exceeds the infiltration rate at all points, average basin rainfall rates can be used. The following example explains the reason for this caution.

---

[16] Hydr. Engr., SCS, U. S. Dept. of Agriculture, Washington, D. C.

TABLE 6.—RAINFALL INFILTRATION AND RUNOFF—A HYPOTHETICAL EXAMPLE

Area[a]	INCHES PER HOUR			15-min runoff (inches)
	Rainfall intensity	Infiltration	Excess rain	
(1)	(2)	(3)	(4)	(5)
A	8.0	2.00	6.00	1.50
B	4.0	1.00	3.00	0.75
C	0.40	0.80	0.00	0.00
D	0.04	0.30	0.00	0.00
Aver.[b] . .	3.11	1.02	2.25	. . . .
15 min[c] .	0.78	0.26	0.56	0.56

Average rain intensity on watershed, in in. per hr....	3.11
Average infiltration on watershed, in in. per hr......	1.02
Average rain excess on watershed, in in. per hr......	2.09
Total runoff for 15 min, in in......................	0.52

[a] Equal size. [b] Weighted average. [c] Amounts for 15 min.

Assume that in a given watershed or drainage area (see Table 6) there are four rain gages serving equal areas of the basin. Each area served by a rain gage has similar physiographic characteristics. The infiltration rates for each area in Col. 3, Table 6, give an average rate on the entire watershed of 1.02 in. per hr. The corresponding rainfall intensity for each area is shown in Col. 2, Table 6, from which the rain excess over infiltration, in a 15-min period, is found to be $(3.11 - 1.02)\,\frac{15}{60} = 0.52$ in., the average for the watershed. On the other hand, the 15-min runoff values in Col. 5, Table 6, indicate a total excess of 0.64 in.

Assuming that the true runoff was 0.52 in., the computed infiltration is $(0.78 - 0.56) = 0.22$ in., or 0.88 in. per hr instead of the weighted average of 1.02 in. per hr. For storms having rainfall rates over parts of the area less than the corresponding infiltration capacity, the computed value of infiltration capacity for the drainage basin will always be less than the actual.

From plats and small watersheds the infiltration capacities for various surface conditions are obtained. If engineers are to use the methods set forth in the paper for applying these infiltration-capacity values to larger drainage systems, it seems imperative that the rainfall records for each gage be applied, through the use of isohyetals for short-time intervals, to the separate drainage units having uniform infiltration capacities.

C. E. RAMSER,[17] M. AM. SOC. C. E.—The science of hydrology as applied to practical engineering problems has been advanced notably by this paper. The method presented is especially appropriate for use in storm-sewer design where large expenditures are involved. With an increase in rainfall and runoff data made available through hydrologic research, no doubt the method can be simplified greatly. This is true particularly in connection with the estimation of runoff from agricultural areas where, quite often, the cost of improvements would not justify a large expenditure for a detailed analysis of the various hydrologic factors.

---

[17] Chf., Hydrologic Div., SCS, U. S. Dept. of Agriculture, Washington, D. C.

LeRoy K. Sherman,[18] M. Am. Soc. C. E.—A large amount of valuable scientific research and study has been made on the phenomena of infiltration since 1930. The use of the coefficient of runoff has been condemned as irrational and erroneous. Little has been presented in applied hydrology that would induce the engineer to discard the coefficient and make use of the infiltration theory. In this connection the authors' paper is timely.

Some of their remarks on variable conditions—"not yet fully agreed on the mechanics of infiltration," "probably never be possible to reduce it to a simple routine," etc.—may lead the reader to the conclusion that the application of the infiltration theory is still too complex to serve as a working tool. It will be constructive, therefore, to emphasize the major elements of the infiltration theory that are now accepted as facts. In the writer's opinion, they include the following points noted by the authors:

(*a*) "* * * curves [of infiltration capacity] all have characteristically similar shapes, * * * relatively high in the beginning of precipitation, decreasing rapidly * * *, and tending to reach * * * definite minimum values * * *" (see heading "Character of Infiltration-Capacity Curves").

(*b*) "* * * the march of infiltration-capacity rates is closely correlated with mass infiltration" (see heading "Infiltration Capacity"). The writer would supplement this item with the following: The curve of infiltration capacity is readily converted into a curve of mass infiltration. In this form it furnishes a simple device for estimating the volumes of runoff due to real or hypothetical storms.[19]

(*c*) Infiltration capacity varies: (4) With vegetal cover (and hence with season); (2) with soil moisture and soil porosity; and (1) little with surface slope (see heading "Character of Infiltration-Capacity Curves").

(*d*) "Infiltration has ceased to be a vague phenomenon; * * * infiltration expressed in terms of infiltration capacity may now be introduced into engineering practice" (see heading "Relation of Precipitation Rate, Infiltration-Capacity Rate, and Excess Rainfall").

The writer concurs with the foregoing statements of the authors. The scientist here can select many exceptional cases, flaws, variations, and inaccuracies in his search for perfection. The engineer, however, will find that these statements of facts, combined with allowable approximations, can furnish reliable working procedures for estimating infiltration and runoff.

The authors' procedure for correlating the periods of observed rain intensities with the curve of infiltration capacity is a practical requirement in the application of the infiltration theory. Their presentation of this detail appears a little involved. Since infiltration capacity decreases with an increase of soil

[19] "The Unit Hydrograph and Its Application," by L. K. Sherman, *Bulletin*, Associated State Eng. Societies, April, 1941.

UNIVERSITY OF MICHIGAN LIBRARIES

moisture in the manner shown by the capacity curve, it follows that the equivalent time T, referred to the capacity curve, is equal to the volume of infiltration divided by the average infiltration capacity. Thus, if rain fell for two hours at an intensity of 0.2 in. per hr, and the infiltration capacity was 0.4 at the beginning of rain, then T, due to the first hour of rain, is $\frac{0.2}{0.4} = 0.5$ hr. At the beginning of the second hour of rain, the volume of infiltration had been increased by 0.2 in. and, by the mass curve of infiltration, this lowered the infiltration capacity to 0.35. For the second hour of rain T is $\frac{0.2}{0.35} = 0.57$ hr. The equivalent value of T for the two hours of this rain is 1.07 hr on the capacity curve. Also, if the rain excess (observed surface runoff) for a storm was 1.5 in., and the derived value of average areal infiltration capacity was 0.3 in. per hr, then the equivalent duration time of the storm $T = \frac{1.5}{0.3} = 5$ hr.

In Part II the authors have described in detail the phenomena and procedure of computing surface runoff from small areas. This is predicated upon the use of curves of infiltration capacity. They have given little space in this paper to the methodology for deriving this curve. They do, however, refer the reader to several papers[8] on the subject.

One of these papers,[20] in the writer's opinion, is a valuable and essential prelude to the authors' paper. The methodology in this article for deriving the curve of infiltration from observed rainfall and runoff applies to small basins in which the downpours of rain are readily correlated with the corresponding volumes or hydrographs of runoff. For small areas, this methodology of derivation is ideal in both simplicity of procedure and accuracy in results. For larger areas, or for small plots on which runoff is measured volumetrically without the hydrograph, the procedure is not directly applicable.

No mention is made, in the paper, of the derivation or use of average areal infiltration capacity. This procedure is in general use. It was first presented by Mr. Horton in 1937.[21] The methodology is simple and applicable to all basins, large or small. On small areas, the initial losses (interception and pocket pondage) may be segregated to give the volume of infiltration and the average areal infiltration capacity (f_a). On large areas, this segregation is generally impracticable. The derived value in this case may be properly termed the "average loss rate" (f_{av}). Studies by the staff of the Illinois State Planning Commission[22] show that reliable capacity or loss-rate curves, and their corresponding mass curves, may be derived from these capacity or loss-rate values.

Attempts have been made by the writer and others to make direct use of these f_a or f_{av} values without subsequent derivation of the curves of infiltration capacity or loss rates. Such attempts, based on averages from unrelated storms, have been futile and misleading. The results are no better than the similar use of a batch of runoff coefficients. Possibly this situation accounts for the authors' silence on the subject of average infiltration capacity.

II, pp. 371–385; also, "Determination of Areal Average Infiltration-Capacity from Rainfall and Runoff Data," by R. E. Horton and R. Van Vliet, Office of Land Use Coordination, Flood Control, U. S. Dept. of Agriculture, November, 1940 (mimeographed).

[22] "Application of the Infiltration Theory to Engineering Practice," *Transactions*, Am. Geophysical Union, 1941 (publication pending).

The authors have made a useful contribution to engineering hydrology. Like all pioneering steps, it can and will be improved and simplified.

A. J. SCHAFMAYER,[23] M. AM. SOC. C. E.—The method of arriving at the rate of runoff from a given area by deducting the rate of infiltration into the soil plus other losses from the rainfall intensity rate is an interesting departure from former methods. The thorough analysis of the large number of variables entering into runoff provides a vivid explanation of the wide variations found in actual runoff for various types of storm. The fact that different agencies, notably the Weather Bureau and Soil Conservation Division of the Department of Agriculture, are gathering more extensive data on rainfall and runoff than heretofore should tend to reduce these errors. Also, the increasing mass of data on stream gaging being secured by the U. S. Geological Survey, in cooperation with various states, should effect further reductions. The present studies by the authors, when compared with these data, will undoubtedly provide further valuable information as to infiltration and the consequent runoff.

The development of the unit hydrograph by LeRoy K. Sherman,[24] M. Am. Soc. C. E., together with the distribution graph by Merrill Bernard,[25] M. Am. Soc. C. E., and the studies in infiltration by the authors and others mentioned in their paper, have added methods by which the designer may make independent checks of his studies of probable runoff.

Also, the authors' careful consideration of the effects on resultant runoff of the varying conditions of surface as to slope, vegetation, method of cultivation, type of soil and its moisture content, and the proportion and disposition of impervious surfaces in any given area, emphasizes the bearing of chance events on any estimate of runoff rates or of the probable frequency of any particular rate.

For the engineer designing storm conduits to carry peak runoffs, a mass of data on simultaneous rain gaging, infiltration, and stream gaging, and simple formulas for its use, should ultimately prove a valuable aid. The material submitted by the authors is a contribution in this direction, since it tends toward removal of one of the unknowns (rate of infiltration) from the coefficient of runoff in the so-called rational formula.

City of Chicago design in recent years has dealt mostly with storm sewers to serve urban areas up to several thousand acres, and the so-called rational formula has been used. The engineer designing sewers or conduits for storm flow is concerned with maximum or peak rates, and, although it is evident that the contribution of the authors may also be of value to engineers concerned with average and minimum rates of flow, the work in Chicago has not been along

UNIVERSITY OF MICHIGAN LIBRARIES

these lines so that those aspects of the study of runoff are not considered in this discussion.

For peak flows, the commonly accepted formula has been

$$Q = C\,I\,A_w \qquad (13)$$

in which, in addition to the notation of the paper, C is the coefficient, I the intensity rate, A_w the watershed area in acres, and Q the peak runoff. After making determinations required by the method proposed by the authors, the equation could be stated

$$Q = (I - L)\,A_w \qquad (14)$$

in which L would represent the rate of loss through infiltration and pondage. This equation might be considered an intermediate step between the so-called rational formula and the equation

$$Q = 10{,}000\,P\,\sqrt{M} \qquad (15)$$

by C. S. Jarvis,[26] M. Am. Soc C. E., or

$$Q = R\,M \qquad (16)$$

as suggested by George W. Pickels,[27] M. Am. Soc. C. E., in which R represents the expected rate of runoff per square mile, M is the area in square miles, and P is a runoff percentage coefficient. With the increasing mass of available data, it may be that, before many years, this last form of equation (Eq. 16) can be used by selecting a runoff factor directly from observed data. This would enable one to avoid both the wide range of probable errors in intensity and frequency involved in applying the rational formula and the extended analytical work involved in the method proposed by the authors. Until such time, however, it will be preferable to use one of the indirect methods.

The application of the infiltration capacity method to a specific problem, as indicated in Part II, will require considerable adaptation and judgment. The type of city block shown in Fig. 8 and used in the hydrographs in Figs. 5, 6, and 7 differs materially from the normal city block in Chicago. The area, shape, and arrangement of the buildings differ. Also, in Chicago the sewers are usually located in the streets in front of the buildings and the roof drainage connects directly to the sewers. This would advance the crest of the hydrograph somewhat in time. However, since the objective of the designer is to determine the peak storm flow, the time factor, which is important in the rational method, loses its importance in the method proposed by the authors. In Figs. 5, 6, and 7, the outflow hydrographs show a notable uniformity of peak flow for the 60-min, 40-min, and 20-min points whether the storm is of the advanced, intermediate, or delayed pattern. The studies of the flow in gutters for streets and alleys are based upon conditions practically identical with the ordinary conditions in Chicago. The equations and curves (Figs. 12 and 13), therefore, could be applied directly to Chicago calculations under similar conditions without changes in factors.

---

[26] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 364.

[27] "Run-Off Investigations in Central Illinois," by George W. Pickels, *Bulletin No. 232*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill., September, 1931, p. 130.

To apply the authors' method, as they have stated, it is necessary to determine infiltration capacity and overland flow for the particular areas entering into the specific problem. This involves determinations of both initial and continuing infiltration capacities and of the precipitation diagram, and it requires considerable additional investigation for many tributary areas with extensive and tedious computations. Therefore, its immediate application for local studies will probably consist of calculations for runoff, using the rational formula with a coefficient of runoff, and checking and comparing the results with results obtained by other methods, including that suggested by the authors, with estimated values of infiltration capacity, overland flow, and for the precipitation diagram adapted from the data and diagrams submitted by the authors.

C. S. Jarvis,[28] M. Am. Soc. C. E.—No matter how commendable the author's purpose may be in attempting to determine surface runoff from rainfall without using coefficients, both the procedure and the objective obtained are subject to challenge—in popular parlance it might be said that the remedy is at least equal to the ills it is intended to cure. Specifically, the obvious implication is that ample data from properly distributed stations are available wherewith to account for the changing intensities and migrations of turbulent centers during the storm period. The painstaking work done in the Soil Conservation Service has demonstrated the wide digressions from point observations ordinarily experienced between stations much more closely spaced than has yet been found practicable on extensive drainage basins. With such spacings of rainfall stations as have been provided over the United States at large, or are now in process, it appears that the authors, in the matter of detail and apparent refinement, may go far beyond the limits of accuracy and reasonable interpretation of basic data, even with such detailed records as they had assembled for a metropolitan center that is especially favored in both length and quality of hydrologic records. It is conceivable that the assumptions involved in the application of this method to less-favored extensive areas by less skilled technicians may include greater errors and uncertainties than some of the more familiar devices.

It is readily conceded that a large army of explorers examining each unit of area in a strange country may ultimately acquire greater volumes and details of information than would a reconnaissance or scouting party; yet comprehensive reconnaissance and rapid scouting with bird's eye views from points of vantage may more nearly satisfy the immediate requirements, and at the same time determine whether the detailed study should be undertaken. Candidly, the writer has deplored the general neglect of voluminous basic data which have been shunted aside during recent years in favor of the microscopic approach, the most satisfactory test and confirmation of which would be the derivation of those same basic data by integration of discharges from elementary areas. Results from individual efforts as well as those of small groups in research projects have brought such returns from a few months' effort as could not be encompassed in years or decades by such procedures as would ban the normal use of coefficients, formulas, and other means of summarizing available observations and experience.

---

[28] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

The data in Table 7, representative samples of extensive tabulations ready for publication, illustrate the advantageous use of coefficients, in this instance expressing percentages of the 5-yr (1934–1938) mean discharges of the Mississippi River and some of its principal tributaries, as well as of some minor tributaries with notable records. The discharges for individual years of the 5-yr period, together with the recorded or estimated means for each period progressively increasing by 5-yr steps up to 30 yr, by 10-yr steps up to 60 yr, thence by 20-yr steps up to 80, 100, or 120 yr according to available data, have provided some fundamentals which could not conceivably be attained except by use of coefficients showing relationships that may be used to bridge gaps in the record. Would it be venturing too far to suggest that the consistent trends and variations from the latest 5-yr means reflected in the percentage coefficients for yearly or longer-period means should provide some guidance for such detailed analyses as the authors have so ably undertaken? Instead of building up exclusively from small increments, using the synthetic method, they would be employing derivations from larger units by analysis of basic data. It would be comparable to making use of the broad perspective views from reconnaissance scouting in order to locate and orient the small plot of strategic importance, and would in no way restrict the detailed studies within the particular plot.

Granting that there is a fundamental difference between the authors' use of instantaneous hydrologic phenomena and the writer's approach through yearly or longer period means, it should be realized that the latter represents the total natural integration of the former, and is fully as susceptible to forecasting, if not more dependable than are the instantaneous or short-period phenomena.

The assertions, such as the authors', that empirical formulas and devices are unscientific and outmoded, including the use of coefficients, do not seem to eliminate them from practice nor from the preferred equipment where basic data are either meager or broken. Surely the results of procedures outlined in this paper may be expressed in the form of coefficients showing what portion of the rainfall appeared as runoff. Whether this percentage is identical with that of excess rainfall or divergent from it, such expression should not be ruled out of reports dealing with hydrologic data. For example, the Ohio River flood volume of March, 1936, at Pittsburgh, Pa., represented about 95% of the rainfall and snow mantle on the tributary watersheds, and about 40% of the total flood discharge occurred on the day of maximum flood. Likewise the Ohio River flood volume of January, 1937, at Metropolis, Ill., represented 69% of the storm precipitation plus the water content of snow mantle, of which not more than 4% was discharged on the day of maximum flood.

Fortunately, the 11-yr record period from 1928 to 1938, inclusive, for Spur, Tex., afforded opportunities for practical tests of runoff determinations by coefficients and by other means. The total precipitation of twenty-eight recorded, runoff-producing storms for this period amounted to 40.89 in., and the observed runoff was 16.26 in. or 40% for watershed No. 1, with 53, 38, 57, and 21%, respectively, for watersheds Nos. 2, 3, 5, and 6. Applying these

[e] Based on all available hydrographs, rainfall records, and other hydrologic data, 1817 to 1938, together with most authoritative evaluations of yearly discharge from Humphreys and Abbot's report and later analyses, supplemented by official discharge measurements for recent years.

[f] Uncorrected quantities derived from the gagings of headwaters and principal tributaries together with estimates for the intervening ungaged areas are enclosed in double parentheses; thus: ((583,814)).

percentages, as runoff coefficients for the respective watersheds for the entire list of twenty-eight storms that produced runoff within the record period, provides a total of 5 × 28 = 140 separate determinations. Comparison of the estimated runoff as derived from those average coefficients with observed runoff resulted in some 41.5% of the number falling within a ± 20% tolerance zone. Variations of the average runoff coefficient by some arbitrary factors designed to take account of the antecedent rainfall, whether copious, moderate, or meager, would increase the items within the 20% tolerance to nearly 70%, or a result comparable to that achieved with the most rigorous, painstaking, and time-consuming analyses of which the writer has knowledge. However, in view of the time, labor, and specialized technical guidance required for the rigorous and complicated analyses, and because of their susceptibility to gross errors not readily detected or controlled, it appears questionable whether the more tedious and detailed methods are justified when comparable results may be had by recourse to runoff coefficients, where in practice the consistency or inconsistency is made plainly apparent along with results.

Perhaps the main divergence of opinion herein expressed has to do with the statement in the final sentence of the "Synopsis" of the paper to the effect that the method is generally applicable to all drainage basins. The writer takes no exception to the use of the most detailed and exacting procedures that can be utilized to advantage in urban or other important or strategic areas where both damages and benefits may be of great magnitude and the necessary basic data from many stations are available. However, to attempt the expansion strictly along those same lines of procedure to cover all drainage basins seems to be an attempt at covering targets entirely beyond effective range of small-caliber weapons. If resort must be had to other devices, there can be no question that these will include coefficients expressing the percentage of rainfall appearing as runoff, either total volume, peak discharge, or average discharge for the critical periods of both storm and flood.

TABLE 8.—EXTENSION OF TABLE 4, CITY BLOCK 4841, ST. LOUIS, MO.

[a] Percentage of mean rainfall rate.

Even where plentiful records are available for rainfall, temperature, soil moisture, surface and cover conditions, infiltration, and all other essential factors capable of influencing runoff, it is well to keep in mind a timely caution from one of the most authoritative technical reports yet published.[29]

> "* * * Because of the existence of impervious or thinly mantled areas most rains, however light, produce some surface runoff, and to this extent the usefulness of the average infiltration capacity as a relative measure of the soil of a given basin to dispose of rainfall is diminished."

Table 4, presenting the results of gagings on a city block in St. Louis, together with the authors' analysis of the actual water losses that occurred for a dozen separate rains, may be extended to show the derived and associated data given in Table 8.

It is significant that the records show variations in mean rainfall intensity for the separate storm periods from 1.14 to more than 4 in. per hr, with storm duration ranging from 10 to more than 60 min, with total depths ranging from 0.63 in. to 3.51 in., and runoff yields varying from 5% to 63% of the rainfall, whereas the "peak rate of runoff from area tributary to alley, in inches per hour," according to the final column of Table 4, averaged 1.62, with extreme variations from 1.00 to 2.45 in. Furthermore, from casual examination, the basic data presented for storms Nos. 1 and 10, Table 8, seem to be so irregular as to warrant review. It is difficult to accept such high infiltration, retention, and peak discharge rates for the same events, depending upon either 5% or 14% runoff coefficient, to produce the momentary peak discharges representing 1.45 and 2.45 in. per hr, respectively. Comparison with the adjacent storms Nos. 2 and 9, Table 8, nearly equal in mean rainfall intensity or in volume of storm runoff, as shown diagrammatically in Fig. 15, indicates the improbability

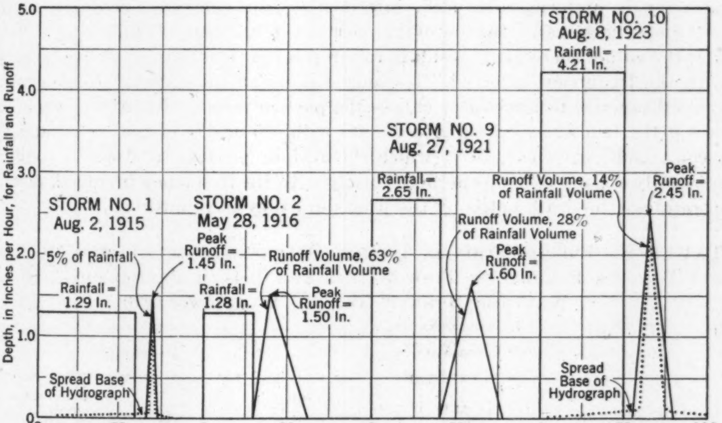

FIG. 15.—DIAGRAMMATIC REPRESENTATION OF RAINFALL AND RUNOFF VOLUMES AND RATES FOR SELECTED STORMS AT ST. LOUIS, MO., DATA FOR STORMS NOS. 1 AND 10 APPEARING TO BE QUESTIONABLE

of such runoff phenomena from the given rainfall. If the time bases of storms Nos. 1 and 10 were extended to cover the rainfall duration or double that period, then (maintaining the same volumes and maxima in accordance with the dotted hydrographs) the runoff peak would necessarily become more needle-like, and would challenge the reliability of the basic data, provided the underlying concepts and procedure of the unit hydrograph are valid. Conceding the fact that the maximum intensity may be much greater than the mean for a storm period, the writer is still unable to accept the 5% and 14% runoff yields of storms Nos. 1 and 10, in association with the peak rates of Table 4.

---

[29] "Floods of Ohio and Mississippi Rivers, Jan.–Feb. 1937," *Water Supply Paper No. 838*, U. S. Geological Survey, pp. 491–492.

It is suggested that the only items inclining to show stability or a definite trend among the quantities of Table 4 are in the final column, and that for those twelve notable storms the average runoff rate might be assumed at its average value with more assurance than may be accorded many of the assumptions underlying the procedure developed by the authors, especially if widespread use is contemplated, apart from their special guidance.

Examination of Table 5, summarizing the results of painstaking studies, drawings shown as Figs. 5, 6, and 7, and detailed analysis by the authors disclose that the mass supply, or rainfall minus infiltration of item 10, Table 5, persistently represents nearly 76% of the total rainfall, varying from 72% to 80% for both the 20-min and 60-min durations, and from 72% to 77% for the 40-min duration, all depending upon the rainfall pattern (that is, whether the intensity is uniform, advanced, intermediate, or delayed, according to the authors' definitions). In view of their admission immediately following Table 5, that the values there used "result in runoff rates greater than would be expected with the frequency involved," it seems almost an unnecessary refinement in general practice to forecast or choose the particular rainfall pattern, when any one of the four types would give results within 5 or 6% of the mean, and the mean runoff coefficient, 76% (which the authors propose to discard), could be so readily altered to conform more closely with the frequency involved, instead of retracing intricate paths by the procedure they have outlined.

TABLE 9.—PRECIPITATION IN INCHES, OBSERVED AT ST. LOUIS, MO., FOR VARIOUS PERIODS OF TIME WITHIN THE 104-YR PERIOD OF U. S. WEATHER BUREAU RECORD, INCLUDING 1940

MAXIMUM AND NEXT THREE VALUES						YEARLY		
3-min	5-min	15-min	60-min	24-hr	Month	Minimum and next three values	Mean	Maximum and next three values
(0.36)	0.59	1.39	3.51	7.02	17.07	23.23	39.23	68.83
(0.34)	0.56	1.19	3.47	5.08	11.43	23.38	....	65.36
(0.33)	0.55	1.03	3.36	4.80	11.26	24.80	....	61.40
(0.31)	0.51	0.92	2.42	4.19	10.90	25.00	....	52.72

The writer has repeatedly gone on record to the effect that the microscopic approach, unduly emphasized, has contributed to the general neglect of the great mass of hydrologic data, and of their readily recoverable values. For example, it has been shown that, in general, the average daily precipitation on days of rainfall (the average annual rainfall divided by the average number of rainy days per year) is a fair approximation to the 3-min maximum rainfall depth at many stations with reasonably long records.[30] Nearly a straight-line relationship on logarithmic paper seems to connect the 5-min, 15-min, 60-min, and daily maximum precipitation, whereas the maximum monthly depth naturally exceeds the maximum daily, and in humid areas often closely approaches the minimum yearly precipitation. Armed with those facts, it is possible to make fair evaluations of maximum hourly or other short-period rainfall intensities to be expected for given frequencies.

Thus the readily available records for St. Louis, Mo., yield the items listed in Table 9. Now, assume that the maximum storm intensities for 24 hr, 60 min, and lesser periods are desired, corresponding to frequencies of 104 yr or other period, or for one half, one third, or one fourth of such periods. They are found in Table 9 in the same order, beginning with the top items.

Rainfall depths for intermediate periods may be derived from their approximately straight-line relationship on logarithmic paper. For any assumed storm pattern with intensities high enough to produce notable runoff, it would seem evident that a fair approximation to the resulting hydrograph could be obtained for city block 4841 in St. Louis, Mo., as follows: By using a time base for the flood rise equal to two or three times the rainfall duration, up to an hour or perhaps two hours of storm; and, by adopting as a first approximation to the maximum ordinate, from 1 to 2 in. per hr (depending on antecedent conditions), subject to such adjustment as shall accommodate from 40 to 70% of the rainfall volume under the outflow hydrograph, and in general accordance with the observed data or derivations from Table 4. A satisfactory approach to estimated runoff may thus be made by the use of coefficients with a minimum of assumption and computations and the maximum support from characteristic behavior of the drainage area, as well as neighboring basins.

It seems to be more reasonable, if not more scientific, to accord due consideration to observation, experience, and the readily understandable empirical expressions that summarize such experience, to serve as controls and safeguards in general on all new methods and technical procedures designed to advance the frontiers of scientific knowledge and achievement.

G. W. MUSGRAVE,[31] ESQ.—If the authors of this interesting paper are successful in doing no more than convincing the great body of technical workers in the field of hydrology of the first point that they make—namely, the fallacy of using runoff coefficients—it is believed by this observer that a genuine service will be rendered. That runoff coefficients are a misconception has been shown by several workers, including LeRoy K. Sherman, M. Am. Soc. C. E., who has noted that runoff is a difference, not a ratio. Despite the evidence that has been presented, this writer feels that the use of this misconception will not immediately be discontinued. For this reason it is desired to present, by way of emphasis, a little additional data, which may be regarded as a more or less random sample of much similar evidence from other locations.

---

[30] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 398; also Fig. 4.

[31] Head, Infiltration Studies, Office of Research, SCS, U. S. Dept. of Agriculture, Washington, D. C.

At the Conservation Experiment Station at Clarinda, Iowa, runoff records have been made for each storm of record since 1932, and for a large number of areas differing in treatments, sizes, slopes, or vegetal covers. In the data cited the runoff measurements are accurate to within 0.01 in. (more probably ± 0.001 in.) and rainfall is recorded by a number of Freiz, Weather Bureau, and special types of rain gages. Table 10 gives the rainfall and runoff for a 3-yr sample period from two areas having similar soil and slope, but differing in vegetal cover.[32] On one of these plots corn is grown annually and on the other bluegrass. It will be noted from the table that the average runoff from the corn for this period was 17.45% and from the bluegrass 2.03%. However, the range in magnitudes is not greatly different, being from 0 to 62.45% for the area growing corn and from 0 to 61.45% for the area in bluegrass. For the area growing corn, fifteen storms produced runoff in excess of 14% of the rainfall. For the area in bluegrass only two storms produced as much runoff as 14% of the rainfall. If one were using runoff coefficients, what value could be selected that would represent each of these two areas satisfactorily? It is obvious that the use of any single percentage to represent the runoff that might result from a given storm on either of these areas would be entirely fallacious.

The authors have indicated a number of the factors that affect infiltration capacity. In connection with the reference to soil porosity, it may be well to mention that it is probable that the total volume of porosity does not affect the rate of infiltration so much as does the pore-size distribution. This is obvious from a consideration of the soil porosity of a fine-grain soil such as clay, which in total volume of porosity usually is relatively large, but in which the infiltration rate is usually low because of the small average size of the individual pores.

[32] "Soil and Water Conservation Investigations," by G. W. Musgrave and R. A. Norton, *Technical Bulletin No. 558*, U. S. Dept. of Agriculture, February, 1937.

In reference to surface slope, also, it may be well to indicate that, although existing evidence indicates little effect of degree of slope upon infiltration, there is evidence indicating that the effect of length of slope commonly is appreciable.

In referring to the variation in initial rates, the authors do not attribute the cause solely to soil-moisture variation, but properly take the broader view and consider "soil condition." To this also might be added the temperature of soil and of water. The effect of antecedent rain upon infiltration is a matter that is of great interest to hydrologists at the present time. Although its effect has been considered by some workers solely as that of filling the voids of a soil profile with water, the authors avoid this misconception. Clearly, the antecedent rain does much more to soil and soil structure than fill the voids with water. The impact of rain drops is such as to apply a large amount of energy to the surface of the soil. During 1941, J. O. Laws[33] provided the necessary basic data upon which the amount of energy of impact may be calculated, and it is apparent that much of the destruction of aggregated soil structure at the surface can be accounted for readily by this ample source of energy.

In addition to these mechanical effects, of course, there are many other effects of antecedent rains. There may be an inwashing of fine particles that lodge in constricted portions of the pores and channels of the upper part of the profile. There is likely to be swelling not proportional to the quantity of water. Also, with the withdrawal of moisture upon drying, the soil does not necessarily return at once to its former structural or permeability status. Actually, direct relations between the content of soil moisture and the amount of subsequent infiltration may be expected only under certain unusual conditions, such, for example, as unigranular sands lying upon impermeable substrata—conditions in which the only effect of water is that of filling voids.

---

[33] "Measurements of the Fall-Velocity of Water-drops and Raindrops," by J. Otis Laws, *Transactions*, Am. Geophysical Union, 1941, p. 709.

At the Edwardsville project of the Soil Conservation Service, which has been mentioned by the authors (Fig. 4), data are available that include repeated infiltrometer runs on a series of ten plots distributed over the watershed. These data include soil moisture at three different depths; and the temperature of soil, air, and water; as well as other environmental conditions. The data on soil moisture and soil temperature for 1940 are given in Table 11.

It will be seen that repeated runs on the same plot do not give infiltration f_c values (the minimum rate of infiltration occurring during the last part of the wet runs) that invariably correlate with soil moisture. More detailed analyses of the data, however, throw a little more light upon the subject. Four successive rounds of determinations were made on each of the ten plots, and the means for each round are presented in Table 12. Here it is seen that infiltration for rounds 2 and 3, which were made during the summer period, is higher than for rounds 1 and 4, during the spring and fall, and that the average soil-moisture content at the 14-in. to 21-in. depth was lower for rounds 2 and 3 than for rounds 1 and 4. However, it is seen also that the temperature of the soil was higher during the summer period, as would be expected. This quadratic or second-degree curve of seasonal trend of infiltration with changing moisture and temperature is statistically significant.

TABLE 12.—COMPARISON OF MEANS OF SOIL MOISTURE, SOIL TEMPERATURE, AND INFILTRATION FOR EACH OF FOUR ROUNDS OF DETERMINATIONS ON TEN PLOTS AT EDWARDSVILLE, ILL. (WET RUNS)

Round	Period (1940)	Infiltration, f_c, in in. per hr	Soil Moisture (%)			Soil temperature (degrees F)
			0 in. to 7 in.	7 in. to 14 in.	14 in. to 21 in.	
1	May 5 to June 6	0.165	26.64	26.28	25.47	65.0
2	June 25 to July 12	0.265	25.48	23.56	22.79	70.3
3	July 29 to Aug. 20	0.210	25.82	24.42	22.89	73.7
4	Sept. 18 to Dec. 20	0.164	26.22	25.22	23.57	54.3

An examination of the results in Table 12, without due allowance for known differences such as time, might readily lead to erroneous conclusions since they appear to show a very strong inverse correlation between moisture and temperature, as well as between moisture and infiltration, and also a strong positive correlation between temperature and infiltration. More detailed analyses of the individual determinations, however, show that the apparent relationship between moisture and temperature is not significant, that the inverse relation of moisture and infiltration is fairly marked for rounds 2 and 3 but not for rounds 1 and 4, and that for the entire series of forty determinations moisture and temperature in combination are strongly associated with infiltration.

One must recognize, however, the strong probability that other variables are involved and the possibility that the rate of infiltration is actually dependent primarily upon such factors. For example, it is known that the pore-size distribution of a soil varies and that it well may be least in the spring and fall and highest in the summer—in other words has the same trend as the seasonal infiltration curve. In these data there are indications not only that changes in both temperature and moisture are associated with changing infiltration, and that under certain conditions one of these variables may appear more important than the other, but also that at the present time the hydrologist may be measuring merely "shadows" of the true causal factor—pore-size distribution.

This example is fairly typical of the effect of soil moisture as it has been found in many studies covering the period 1929 to date (1941). Briefly, it may be stated that ordinarily:

(*a*) Seasonal trends of soil moisture and soil temperature tend to be correlated inversely;

(*b*) Infiltration is lower when soil moisture is higher, but the magnitude of reduction is not proportional to the increase in moisture;

(*c*) Subsoil moisture often shows a more marked effect upon infiltration than does soil moisture in the surface;

(*d*) Seasonal trends (similar to those of Table 12) ordinarily are statistically significant; and

(*e*) There are continuing evidences that other factors in addition to that of soil moisture are exerting their effects upon the rate of infiltration.

Looking at the matter from a purely physical basis, there seems to be no reason why one should commonly find mathematical proportionality relations between soil moisture and infiltration, since obviously soil moisture alone is not an adequate basis for expressing the size of soil pores. Perhaps the additional variables in the complex may be identified and measured during the course of some of the many investigations now under way.

Messrs. Horner and Jens have been making studies of rainfall and runoff for some time and have had opportunity to test, under many conditions, the analytical procedures that they have presented. In their example of a rational procedure without the use of runoff coefficients, they have presented material that should be distinctly useful. The writer agrees with them wholly in principle, and merely suggests caution against oversimplification in the handling of some of the variables, the effects of which are undoubtedly highly complex, and the magnitude and effect of which are only now being investigated.

F. L. FLYNT,[34] ASSOC. M. AM. SOC. C. E.—In their detailed analysis of storm-water runoff from typical urban areas, the authors have demonstrated beyond reasonable doubt that it is more rational to consider runoff as rainfall minus losses than it is to assume that runoff may be expressed as a constant percentage of the rainfall for a given storm. They have also demonstrated that it is practicable to use this principle in the design of drainage systems. The application of the equations for overland flow and the routing of the resulting hydrographs through alley and gutter storage introduce a new technique in the analysis and synthesis of runoff from urban areas.

---

[34] Associate Engr., U. S. Engr. Dept., Rock Island, Ill.

It is evident that the refinements introduced into the design procedure, through a more complete understanding of the fundamental principles involved, tend to increase the work required to design a given drainage system, but this is not a valid argument against the use of the improved method. It would be just as logical to ignore secondary stresses in the design of large framed structures or to provide for them by an arbitrary increase in the factor of safety. The old saying "Anything worth doing at all is worth doing well" applies to the design of engineering structures as well as to lay activities.

Perhaps the weakest link in the chain of the demonstration is the first of the six essential stages of design as listed in Part I under "Application to Hydraulic Engineering"—namely, the delineation of the precipitation pattern. This weakness is not inherent in the method but is due to the present lack of information that further research may some day supply. So far as the writer is aware, no determinations have been made of the relative frequency of various types of storm patterns, such as "advanced," "intermediate," and "delayed," which would enable a satisfactory choice to be made, appropriate to a given design frequency. Fortunately, the effect of rainfall pattern upon the maximum rate of runoff is less apparent in the hydrograph of outflow from a drainage network serving a large area, where the time of concentration is comparatively long, than it is for a single block. This is made clear from a study of Figs. 5, 6, and 7.

The detailed method of analyzing the hydrograph of runoff from urban areas, as demonstrated in the paper, is equally applicable to the problem of designing drainage structures to carry surface runoff from airport areas. Such an analysis, when the grading layout is closely coordinated with it, enables a balanced design to be made that not only assures an adequate drainage system, but also one which is the most economical for the given conditions.

In the analysis of stream-flow hydrographs, the fundamental principle of considering runoff as rainfall minus losses rather than as a ratio or coefficient is rapidly coming into general use. The methods of analysis in the case of drainage areas, involving many square miles, of course, are quite different in detail from the examples given in the paper. The reasons for this difference may be outlined as follows:

(*a*) In the case of streams the volume of water in storage as overland flow or surface detention is usually quite small when compared with water in channel storage.

(*b*) Time periods of hours, rather than minutes, must be used, which means that loss rates must be averaged not only over large areas but also over comparatively long periods of time. This makes it more difficult to relate the observed loss rates with the infiltration capacities of the various soils in the area.

(*c*) The infiltration rate for a stream basin varies over a wider range than it does for urban or airport areas. This is due to the fact that in agricultural areas the condition of the top layer of soil is modified from season to season and from year to year through cultivation and changes in vegetal cover.

(*d*) Because of the present lack of an adequate method of segregating the various kinds of water loss, the experimental values of loss rate as determined from a comparison of rainfall and runoff volumes do not, necessarily, reflect the true value of infiltration loss but the aggregate of all losses, whatever their nature.

(*e*) Another disturbing factor, common to stream basins but insignificant in urban areas, is ground-water return to the flood hydrograph. The problem of segregating the ground-water and surface-water hydrographs has not yet been completely solved. This is partly because there is often no sharp line of demarcation between the two. Some of the ground water travels underground only a few feet before appearing in stream flow, whereas some of it travels through subsurface strata for great distances.

(*f*) Uniform rainfall over small urban areas may be assumed, but for large areas uniform rainfall of significant intensity is practically unknown. The areal distribution of rainfall becomes increasingly important as the size of the watershed increases. Cases have been observed in which appreciable abnormalities in the shape of runoff hydrographs have been traced to heavy rainfall which had been unofficially observed over limited areas, but which had not been recorded at any Weather Bureau Station.

The effects of all the aforementioned conditions, which tend to complicate the rainfall-runoff relation, become more pronounced with the increase in size of the drainage area. It follows that, for the purpose of analyzing hydrographs of record and for synthesizing design floods, it is advisable to subdivide the drainage area into sub-basins and to subdivide the rainfall into periods as short as practicable, noting the areal distribution of rainfall for each period over each sub-basin. By the use of synthetic unit graphs where no hydrographs are available, and by routing and combining the hydrographs of the various sub-basins, hydrographs of past floods may be reconstituted with reasonable accuracy from the rainfall data, and design floods may be synthesized from assumed or transposed rainfalls with more confidence than if large basins were considered as a unit. The amount of work involved in this procedure is considerably greater, of course, than when the older methods are used; but the more reliable results justify the increased work.

Thus it is seen that the principle of breaking down the area tributary to the point of measurement into simpler components for the purpose of analysis and synthesis of runoff hydrographs is of general application and, no doubt, will eventually become the standard practice as will the evaluation of runoff as rainfall minus losses instead of in terms of the percentage factors formerly used.

W. I. HICKS,[35] ESQ.—A comprehensive outline of a method of computation, based on the analysis and synthesis of the factors governing runoff from a city block, is presented in this paper, which points the way to an extension of the computation to a complete drainage system. On account of the wide scope of the subject and the limitations of space, the text must be read carefully to enable one to grasp the entire subject matter.

---

[35] Asst. Civ. Engr., Storm Drain Div., Bureau of Eng., Los Angeles, Calif.

The writer has been investigating rainfall-runoff phenomena in Los Angeles, Calif., for a number of years, with the result that a schedule of procedure identical with the six stages listed by the authors (see heading "Application to Hydraulic Engineering") was evolved:

I—A precipitation pattern between "intermediate" and "delayed" was selected;

II—The infiltration curve was based on small test plots and the analysis of rainfall-runoff records gathered from local drainage areas (see Fig. 16);

III—Antecedent precipitation was determined by probability studies and used to weight the basic infiltration curves;

IV—Net rainfall curves were derived for different classes of development after consideration of—

V—Infiltration curves, depression storage varying from 0.10 in. for heavy soils to 0.20 in. for sand; and

VI—The net rainfall curves were translated into hydrographs after consideration of the various forms of detention.

The summation-of-hydrograph method of computation is well suited to Los Angeles terrain where the intensity of a storm of given frequency varies as much as 2 to 1 in a single drainage area; the reason for the variation is the mountainous character of a part of the area.

Apart from the agreement in the general principles, there were some variations and differences on various details of more or less importance.

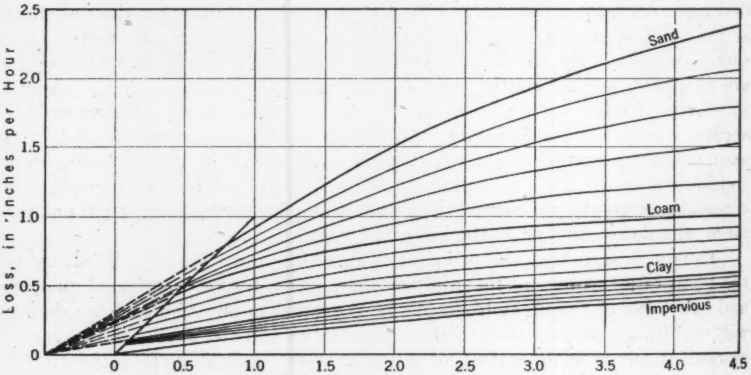

FIG. 16.—RAINFALL RATE—LOSS RATE CURVES

In delineating the precipitation curve, the mass curve was used in preference to the intensity diagram because it was believed that the volume of runoff was of major importance. Likewise, the influence of detention was introduced by suspending the varying depth of storage under the net rainfall curve; and the time functions of the hydrograph were approximated by analyses of hydrographs from drainage areas of various sizes and stages of development.

The general shape of the authors' infiltration-capacity curve is in agreement with local data. Analyses of rainfall-runoff records for a four-day storm culminating on March 2, 1938, show a downward march in capacity to practically zero (the zero capacity was a combination of low infiltration and seepage flow). Because the local rainy season comes in the winter when evaporation is low, because of the delayed position of the peak rainfall, and because of relatively high antecedent precipitation, the flat part of the curve is used, whereas the authors use the sharply descending part of the curve for the "thunderstorm" which breaks a hot, dry period.

The curves in Fig. 16 differ from the authors' assumption of comparative independence of rainfall intensity under turf cover in that the higher intensities of rainfall produce a more complete coverage of the imperfect plane surface of urban yards and so increase the infiltration capacity.

In the authors' typical block, they assume that drainage from impervious surfaces does not flow over turf on its way to the gutter or alley. Analysis of the various classes of urban residential districts indicates that walks, driveway strips, and small porches usually discharge on to turf and that many roof downspouts discharge into flower beds; the total of these areas average from 15% to 20% of the entire area. If this assumption is granted, the gross rainfall for the pervious area is increased by the runoff from these areas, and the impervious supply volume is diminished correspondingly.

In the matter of overland flow and surface detention, limited experimental data were taken locally. The results of the experiments are included for the purpose of discussing the paper and to make them available for use.

The apparatus consisted of:

(1) A rectangular wooden trough 100 ft long by 0.96 ft wide mounted on a series of wooden standards and capable of being adjusted to different slopes.

(2) A 2-in. galvanized pipe, capped at both ends and tapped at intervals to receive nipples, mounted in the wooden standards above the trough. Below this pipe and connected to the nipples were suspended brass sprinkler pipes with close-spaced sprinkling orifices.

(3) A hose connection made from the 2-in. pipe to the valve of a 100-gal tank on a platform set uphill from the apparatus.

The types of surfaces tested were:

(*a*) Tar and sand corresponding to tar-paper roofing, sidewalk, concrete paving, and similar surfaces;

(*b*) Tar and gravel corresponding to the roofing of that type and rough-finish asphaltic concrete paving; and

(*c*) Clipped sod selected as being representative of the average city lawn. Tar-paper baffles were set flush with the ground surface to prevent subsurface flow.

Slopes used varied from 0 to 7%. Lengths of flow were 100, 50, 25, and 10 ft. (The 10-ft runs were on a 10-ft by 10-ft adjustable platform.) Uniform rates of simulated rainfall varied from 0.5 to 7.0 in. per hr.

Data from these tests have been filed in the Engineering Societies Library.[36]

---

[36] 29 West 39th Street, New York, N. Y.

They are quite erratic for the tar and sand surface on account of inability to maintain a true plane for so smooth a surface; the data for the other surfaces are more rational but require judgment for interpreting. The data were plotted on logarithmic paper and the following exponential formulas were derived:

Tar and Sand Surface.—

$$\delta_a = \frac{0.0136\, l^{0.318}\, \sigma^{0.535}}{S_0^{0.4615}} \qquad \text{(17a)}$$

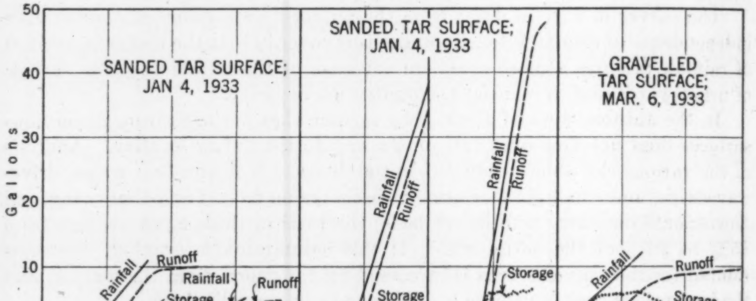

FIG. 17.—SAMPLE RUNS (TROUGHS, 100 FT BY 1 FT; AND S_0 = 0.03)

and

$$t_c = \frac{1.3\, l^{0.323}}{S_0^{0.448}\, \sigma^{0.64}} \qquad \text{(17b)}$$

Tar and Gravel Surface.—

$$\delta_a = \frac{0.0257\, l^{0.384}\, \sigma^{0.351}}{S_0^{0.367}} \qquad \text{(18a)}$$

and

$$t_c = \frac{2.23\, l^{0.373}}{S_0^{0.366}\, \sigma^{0.684}} \qquad \text{(18b)}$$

Clipped Sod Surface.—

$$\delta_a = \frac{0.078\, l^{0.322}\, \sigma^{0.325}}{S_0^{0.281}} \quad \text{(19a)}$$

and

$$t_c = \frac{9.34\, l^{0.298}}{S_0^{0.302}\, \sigma^{0.785}} \quad \text{(19b)}$$

Except that S_0 denotes slope, as percentages in Eqs. 17, 18, and 19 (and in Eqs. 20*a* and 20*b*), the symbols used are those of the paper, t_c being measured from the beginning of the supply rate to the point of full runoff and S_0 = slope expressed as a percentage. It is to be noted that not the marginal but the average depth is used. Nomographs were designed for the convenient solution of Eqs. 17 to 19. Sample runs are shown in Fig. 17.

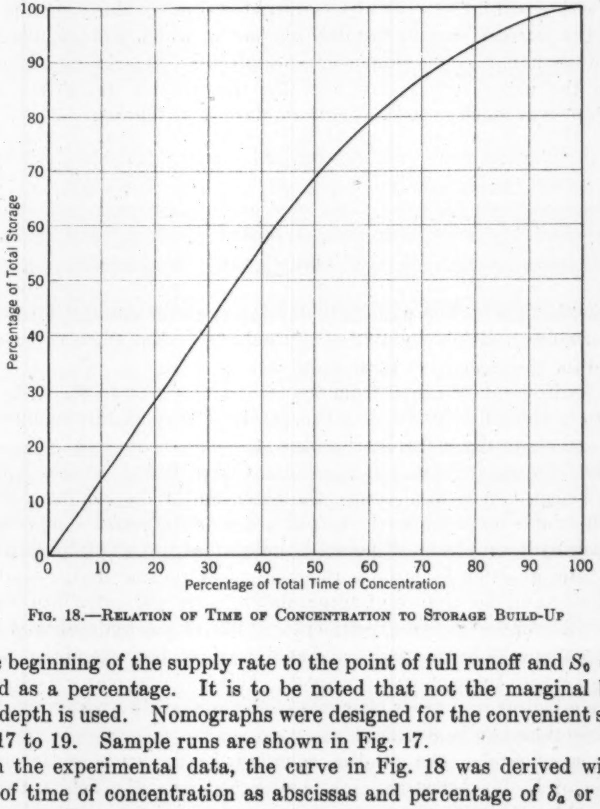

FIG. 18.—RELATION OF TIME OF CONCENTRATION TO STORAGE BUILD-UP

From the experimental data, the curve in Fig. 18 was derived with percentage of time of concentration as abscissas and percentage of δ_a or storage as ordinates. It was based on data from a variable-flow trough, a clipped sod plane surface, a tar and gravel plane surface, and a tar and sand plane surface. With these formulas and their corresponding charts, the alteration of the hydrograph of supply after flow over a plane surface can be computed as outlined in the paper (between Eqs. 4 and 5) except that a mass curve of supply and varying depths of storage are used instead of a supply-intensity curve and the variation of intensity of runoff from the plane surface.

Results obtained by the two methods of treatment are consistent for all practical purposes. When one considers the unavoidable variations in roughness of surface of roofs, pavement, and turf, and the necessary assumption of average conditions, precise mathematical treatment is not to be expected.

In determining the effect of gutter storage on the hydrograph, the writer has followed the general principles stated by the authors. Two formulas similar to those for plane surfaces were computed on the basis of a 30-ft roadway ($n = 0.012$) with a 4.5-in. crown and no crossfall, which was selected as representing average conditions. A series of tests was performed on a V-shaped trough with equal increments of flow introduced at regular intervals along its length; the purpose was to test the manner in which storage was built up. The run on a flat grade supported the authors' remarks on the difference between the water-surface slope and the construction grade; the upstream water slope was much flatter. The formulas are as follows:

$$\delta_a = \frac{0.00044\, l^{0.697}\, \sigma^{0.794}}{{S^{0.417}}_0} \quad \text{(20a)}$$

and

$$t = \frac{0.0443\, l^{0.732}}{{S^{0.39}}_0\, \sigma^{0.252}} \quad \text{(20b)}$$

in which t is time of flow with fully developed gutter storage; for t_c as in the other formulas multiply by 1.33 ±. Similarly to Eq. 19, a nomograph was designed for the solution of these formulas.

The hydrograph of runoff from the lot is transposed to the hydrograph of inflow to gutter inlet by varying the gutter storage in the manner outlined by the authors in the text following Eqs. 4.

Under "Summary and Conclusions: Conventional Urban Areas," the authors suggest, in general terms, the extension of the computation beyond the hydrograph for a single block; paragraph (*e*) indicates a process of summing such hydrographs at all points of inflow (see also text following Table 4). If this interpretation is correct, the volume of routine design work will be considerable and the chance of accumulative error will enter into the computations. A comprehensive experimental study of the hydraulics of the flood wave, confluence of hydrographs, and analytical comparisons of the hydrograph of the block with those of drainage areas of different sizes may yield information as to time factors and other elements of the composite hydrograph by which these objections can be avoided.

Acknowledgment.—The studies reported herein were made under the direction of L. W. Armstrong, M. Am. Soc. C. E., the field activity being supervised by H. W. Fraim.

ALBERT S. FRY,[37] M. AM. SOC. C. E.—The authors have made a valuable contribution to a field of hydraulic engineering which, in many respects, is in a pioneer phase of development, with arguments pro and con as to the practical usefulness of infiltration theory and procedure. Progress in this field will be made as basic knowledge accumulates and as engineers become better acquainted with infiltration and its advantages and limitations.

---

[37] Head Engr., Hydr. Data Div., TVA, Knoxville, Tenn.

It is to be regretted that the paper deprecates past work in hydrology and glorifies infiltration as a new method that puts hydraulic design on a parity with structural steel design in exactness. It is true that the network of stream gages and rain gages has expanded in certain areas of the United States in recent years, providing valuable information of particular use in those areas. The authors expect this to revolutionize engineering practice but overlook the fact that much of the new data are of limited local application and that overenthusiasm in some places has produced data of dubious value. To imply (as the paper does) that, in the past, design of important hydraulic structures has been "based on crude over-all general relationships in the hydrologic field," shows a lack of appreciation and recognition of the invaluable contributions made by men such as C. S. Jarvis, M. Am. Soc. C. E., and others working in this field. Hydrologic data—both past and present—are seldom available on any project to the extent that the engineer desires, but this has not prevented him from understanding hydrologic fundamentals. He has not only understood them but has recognized their limitations in practical application probably better than the disciples of the new order of infiltrationists. Real progress is not achieved in any field by exorbitant and unwarranted claims.

The paper presents the method for surface runoff determination as it relates specifically to urban storm drainage but also recommends it as generally applicable to all drainage basins, and states that it provides a more logical and dependable basis of design for important hydraulic structures than has heretofore been considered feasible. This is more likely to be true of urban storm drainage than of large-scale uni-purpose or multi-purpose projects. The former deals with relatively small areas of physical characteristics susceptible of fairly close determination under detailed study, and design is predicated upon relatively short-time intense rainfall. The latter embraces large watersheds of complex physical and hydrological characteristics difficult of determination, and design is based upon rainfall over a longer period of time.

These large water projects involve extensive works such as reservoirs, channel improvements, and levees, and it is doubted that a more logical and dependable design for these works can be made by substituting infiltration for previously used methods. Such projects must be designed for maximum flood conditions, allowing a factor of safety that might erroneously be considered to be a factor of ignorance, whereas actually too much engineering judgment and experience are involved to apply the term "ignorance." During storm periods that cause maximum floods, the rate of runoff is high—in many cases 90% or more of the rainfall. Infiltration is a relatively minor part of the total rainfall during such great storms and hence is not a primary factor in determining the design basis for a uni-purpose project such as flood control or a multi-purpose project involving flood control, hydroelectric power, navigation, and other purposes.

There is as yet no sound method of estimating accurately the size of the maximum possible storm. Attempts to do this have been made in recent years and represent a forward step in the right direction. However, meteorological scientists, such as J. Bjerknes and C. G. Rossby, do not consider that the science has yet advanced to the point where the factors which produce maximum storms can be closely evaluated so that the maximum storm for a given region can be determined with any degree of reliability. If it were possible to know the maximum storm for which to design, then there would be more justification for the application of infiltration methods. Even in that case, for large areas approaching or exceeding 1,000 sq miles, for proper application of infiltration methods detailed information would be needed for the entire watershed regarding hydrologic factors, physiography, geology, and land use and management, including both agriculture and forestry. Approximations and estimates would have to be made at various steps, and the end result would not be any more sound than it would be by the methods heretofore used by competent hydraulists.

The authors' statement (see heading "Application to Hydraulic Engineering: III—Adjustment of Infiltration-Capacity Values to Antecedent Conditions and Precipitation Pattern") that infiltration procedure allows "the use of much lower factors of safety than one involving a choice of a coefficient of runoff" is not in accord with established facts. Until the engineer can know with certainty the maximum storm that may be expected, there is no basis for expecting infiltration analysis to justify lower safety factors.

The files of the Miami Valley Conservancy District, and its technical publications, will show that the hydraulic engineers, headed by Sherman Woodward, M. Am. Soc. C. E., in charge of the design of the noteworthy flood-control reservoirs and channel improvements in the Miami Valley in Ohio were fully aware of infiltration and other hydrologic factors that are woven into the fabric of the infiltration theory advanced during the past few years. The paper refers to the Miami District research on small plots. Such experiments were made and reported upon by Ivan E. Houk, M. Am. Soc. C. E. They served to evaluate the characteristics of the particular plots, and were interesting within themselves, but furnished no basic information used in the project design. In that District, as in any other large water-control project, the design must provide for storms the size of which, in the final analysis, must be based on the best engineering judgment of a competent engineering staff, supplemented by qualified consultants. Such a determination is a practical integration of hydrologic relationships based on mature consideration of all factors involved.

In the design of flood-control works in the Tennessee Valley to provide protection to the City of Chattanooga, and in determining flood-control capacity in the Kentucky Reservoir at the mouth of the Tennessee River as a link in the flood-protection works for the Mississippi Valley below Cairo, Ill., a board of consulting engineers was called in to work with the Authority's engineers in determining the basis for design. This Board consisted of Daniel W. Mead, Past-President and Hon. M. Am. Soc. C. E., the late Harrison P. Eddy, Past-President, Am. Soc. C. E., and Gerard H. Matthes and Ivan E. Houk, Members, Am. Soc. C. E. The judgment of this Board (plus that of the Authority's own engineers, including Joseph H. Kimball, James S. Bowman, and Mr. Woodward, Members, Am. Soc. C. E.) developed design criteria supported by long and successful engineering experience and practice. It is scarcely conceivable that any infiltration derivative could be substituted for the considered decisions of such an engineering group.

The Tennessee Valley Authority has under preparation a plan for flood control for the French Broad River Basin in western North Carolina, an area of about 1,800 sq miles, including the City of Asheville, industrial properties of great value, and a rich agricultural area. A study is being made of the effects of improved land use and better farming methods on flood flows and water conservation in this region. Since 1935 the Authority has conducted an agricultural test program in this watershed involving more than 100 test demonstration farms. It has been clearly demonstrated that, by better land management and the proper application of lime and phosphate fertilizer, definite improvement in infiltration rates and capacity has been brought about that can be evaluated quantitatively in its effect on flood peaks and volumes. However, it is extremely difficult to make practical use of this fact in flood-control design, although supported by concrete information, because the engineers themselves cannot say with positive knowledge just how big a storm should be the basis for flood-control design. Whatever the basis finally determined upon, it must be the best judgment of the engineers and must be large enough to be amply safe to protect the valuable city and industrial properties involved. It would be foolish to apply a method to the extreme flood—the design flood—which might result in lowering the peak a matter of inches when the size of that flood must be estimated with the probability of considerably more error than the total beneficial effect of improved cover under good land management.

The authors recommend aerial photographs for land-use information to determine percentages of land within a watershed having particular types of vegetal cover, such as forests, pastures, and cultivated land. The Tennessee Valley Authority has made extensive use of aerial photographs in its mapping and other programs and has available excellent aerial photographs of the entire 41,000 sq miles in the Tennessee Valley. It is possible from these photographs to determine the percentage of open and forested lands, but for infiltration purposes much more than this is necessary. However, there are great differences in lands with respect to infiltration capacities that cannot be discerned from aerial pictures no matter how good these may be. For example, it is impossible to determine, from the aerial photographs, the extent to which a forest canopy is complete or the amount and character of litter under the trees. Woodlands used for pasture have quite different infiltration characteristics than woodlands not so used, yet both would appear the same in an aerial photograph. In studying the effects of land use on flood control in the French Broad watershed by infiltration methods, it has been necessary for foresters and agriculturalists to go into the field and classify the various types of land use into a number of different classifications for each major usage. Even this work has had to be generalized because of the large watershed involved.

The paper also states that soil maps are available for a large part of the

United States. This is literally true, but it fails to tell the real status of the soil surveys. These are of three general types. There are the reconnaissance maps, covering large areas, which are so generalized that they do not provide the detailed information desirable for infiltration procedure. Detail surveys by counties are available for only 35% of the land area of the United States. There are the much improved detail surveys issued only in the last few years for a small number of counties. The last two types are valuable in providing useful information for infiltration studies, but these are not available for about two thirds of the country.

The unwary and unknowing would be led to believe that with aerial photographs and soil maps it is a simple matter to classify the land-use and soil characteristics of a drainage basin sufficiently for a satisfactory application of infiltration. Experience in application belies this impression. It is this kind of statement that leads thinking engineers to discount infiltration as a useful engineering tool, and it is unfortunate that the infiltrationists have adopted this technique.

From this discussion so far, it may appear that the writer is an "anti-infiltrationist" but, as a matter of fact, he is enthusiastic about the possibilities of this method when used in its proper place. Infiltration has a definite and most useful application in a field not mentioned by Messrs. Horner and Jens. This field is exemplified by the water-control operations of the large system of multi-purpose reservoirs in the Tennessee Valley. The system now (1942) numbers sixteen reservoirs and nine more are under construction so that the dispatch of water through these reservoirs, operated as one integrated system, is quite complex. A group of especially trained hydraulic engineers make detailed determinations of stream flow each day, including both surface and subsurface runoff, from ungaged areas. The efficient operation of the system requires continuous close knowledge of water available throughout the Tennessee Valley in numerous headwater streams and in local areas tributary to the reservoirs. In this work of daily river-flow predictions and water-control operations, infiltration has large possibilities. The condition of sub-basins with respect to physical and geological characteristics, ground-water levels, field moisture, cover, and land use can be known in advance of rain so that, when the rain comes, these facts can be considered and infiltration methods used to estimate storm runoff. The ordinary storm is not the great storm for which the dams and other works are safely designed, but rather the one that is likely to occur at any time, depending upon the season of the year. In this class of rains, where infiltration may account for a considerable part of the rainfall, the method is of real importance and affords a logical approach to the problem of estimating runoff.

W. W. Horner,[38] M. Am. Soc. C. E., and S. W. Jens,[39] Assoc. M. Am. Soc. C. E.—The discussion of this paper is particularly interesting with respect to the wide range in the items that apparently attracted the attention of the different discussers, and in the variety of viewpoints expressed.

[38] Cons. Engr. (Horner and Shifrin), St. Louis, Mo.

[39] Associate Consultant, W. W. Horner & H. Shifrin, St. Louis, Mo.

The discussions of Messrs. Jarvis and Fry are from the viewpoint of the application of the method to large drainage basins. Since this matter was not presented in detail in the paper, these are primarily discussions of the writers' statement that "The method is presented as being generally applicable to all drainage basins, and is described in detail as it would be used in urban storm drainage" (see "Synopsis"). The writers had no intention of suggesting that the method described in detail for urban storm drainage would be duplicated in its details in an application to a large drainage basin, but rather that the principles involved and the general type of methodology, if adjusted to a different scale, were so applicable. The matter of a similar, but somewhat differently adjusted application to a large drainage basin, has been prepared.[40]

Mr. Fry's discussion appears to be largely a defense of hydraulic practice of the past. He apparently reads into the paper a condemnation of the persons who have been involved in this practice, which was not expressed or intended, or even inadvertently implied. The writers wish to make it quite clear that they have the greatest respect for the men who have been, and who still are, providing the best possible designs for important hydraulic projects on the basis of data that are far from adequate for the purposes.

One of the writers had a responsible part in the development of the so-called "rational method," a method which they have stated that they expect to see supplanted by some procedure similar to that presented in the paper. The rational method represented an important improvement over prior practice, but they would feel derelict to the profession and to themselves if they did not make use of any new data as they became available, and of improvement in technique recently found to be possible. The so-called "rational method" is a good example of the use of "crude over-all general relationships," in that it attempts to relate peak surface runoff rate to mean rainfall rate through a judgment coefficient.

Mr. Fry's primary objections to the method outlined in the paper appear to relate to its possible use as a basis of spillway design, and are on the ground that little is known about maximum storm potentiality and therefore that hydrologists are not justified in attempting a detailed evaluation of the possible maximum flood.

The writers regret that the recent and very proper concentration on the problem of maximum flood flows has relegated to a secondary status the problem of evaluation of flood flows in terms of specific frequency of occurrence, as this phase is a very important determinant in the greater number of hydraulic projects and problems that have a hydraulic background. Some of these are mentioned in the last paragraph of Mr. Fry's discussion.

Mr. Fry also apparently read into the paper a suggestion that the better present coverage of the United States by airplane photographs and by maps of various types would make it possible to evaluate flood flow without going into the field. No such suggestion was intended, and his further elaboration of the field procedure that would be required is a valuable contribution to this phase of the discussion.

[40] "Rôle of the Land During Flood Periods—Relations Between Rainfall and Stream Channel Inflow," by W. W. Horner (publication in *Proceedings* pending).

Mr. Jarvis breaks a gallant lance in defense of the castigated runoff coefficient, particularly with reference to the writers' statement that the method is generally applicable to all drainage basins. Admittedly, if the available and reliable statistical data for a particular large drainage basin reveal a consistent relationship as to the particular quantities under study, any hydraulic engineer would lean heavily upon such data; but if the magnitude and economic importance of the proposed project are great and there exist sufficient data on rainfall, cover, soils, infiltration capacities, and channel storage discharge characteristics, or if adequate unit graphs can be developed, an application of the principles suggested in the paper can be made to units of, say, less than 1,000 sq miles. The resulting hydrographs can be integrated by ordinary methods to produce a reasonably accurate representation of the flow at the point under analysis, not only as to total runoff or yield but as to momentary peak and durations of rates of various magnitudes. For basins of several hundred thousand square miles, it can be understood that the detailed calculations would be unwieldy; but it is submitted that, for basins with a tributary area of as much as 20,000 sq miles, it is worth while to attempt to evaluate the production of net rainfall as it most probably occurs in nature, hour by hour or in lesser or greater time units as the facts may justify. Such an approach would certainly result in greater reliability than a purely statistical approach.

In the problem used to illustrate the principles, as in most urban storm drainage, peak values are of greatest importance, and no single coefficient would reflect properly the varying runoffs resulting from the different precipitation patterns. The peak resulting from the uniform pattern, it should be noted, differs by much more from any one of the peaks due to the other three patterns (all more likely of occurrence in nature) than any one of the other three peaks differs from either of its two fellows.

Mr. Jarvis presents, in Table 7, some extremely interesting and important data with respect to the variation in annual yield of the Mississippi River and its principal tributaries. The writers agree with the importance of statistical analysis and the use of correlations and factors in organizing data of this class, as such factors are not of the same order as the "coefficients" referred to in the paper. The data presented in Table 7, however, seem otherwise to be scarcely pertinent to the subject of surface runoff in its flood phase as presented in the paper.

Mr. Jarvis sets up runoff coefficients (volumetric) for the Spur, Tex., data, and shows that by varying these coefficients through arbitrary factors their application will reproduce runoff volume for 70% of the storms within a 20% tolerance, a degree of significance that is certainly not impressive. If rate coefficients had been used, the results would have been equally poor. It is interesting that Mr. Musgrave presents similar data from Clarinda, Iowa, to show that "It is obvious that the use of any single percentage to represent the runoff that might result from a given storm * * * would be entirely fallacious." Mr. Jarvis' quotation from *Water Supply Paper No. 838* may serve to clear up a matter that Mr. Sherman also discusses. When losses occurring on only part of a basin are divided by the entire basin area, there results an arithmetical quotient that has no relation to infiltration capacity, areal or otherwise. This situation has been covered by Messrs. Horton and Sherman in presentations before the American Geophysical Union.

Mr. Jarvis' difficulty in accepting the data in Table 4 apparently results from a misunderstanding of what the figures mean. The losses shown as infiltration plus retention practically all occur on the 70%-of-pervious area, and have been reduced to inches of depth in that area, whereas the peak rates include the flow from the 30%-of-impervious area. A study of the relation of these two would require a much more complex approach than that which Mr. Jarvis attempts to use. The writers do not quite understand the reason for the presentation with respect to St. Louis precipitation. There is a long and accurate record of precipitation at St. Louis that has been analyzed many times for the determination of rainfall frequency. It is not presumed that Mr. Jarvis is suggesting that hydrologists approach this matter through a general correlation, when the detailed physical data are available at the site.

Mr. Musgrave's opening paragraphs and his presentation of the Clarinda data support the writers' thesis with respect to the desirability of substituting more accurate methods for coefficients of runoff. His further discussion on the present knowledge of infiltration and infiltration capacity, and on the factors controlling them, is extremely important. The research he mentions is particularly interesting with respect to the efforts to compare infiltration values with antecedent soil moisture and soil temperature. The practical need is very great for some easily applied relationship between infiltration values and one or more controlling variables, readily measured or obtained from normally available data. Another important part of the mechanics of applying infiltration-capacity curves involves a determination of rate of recovery of infiltration capacity for each soil and cover under varying conditions of antecedent infiltration and varying intervals of time between rainfall blocks within a storm itself. The sort of research that Mr. Musgrave indicates is under way will undoubtedly throw helpful light on these and other problems which require satisfactory and practical solutions. However, the writers believe that present knowledge of infiltration capacity and the ability to produce average curves for various complexes and for various seasons, and to recognize variations of infiltration capacity concurrently with, even if not controlled by, changes in soil moisture, justify hydrologists in using the established curves in engineering practice with some confidence.

Mr. Ramser holds out the encouraging expectation that the methodology of applying the latest hydrologic knowledge to engineering problems will undoubtedly be "simplified greatly."

Mr. Harrold's discussion is helpful, both as to his general comments on the methodology proposed and for his emphasis on the necessity of applying it to basins separately by rainfall centers, and separately by soil and cover complexes. The writers agree with him that the use of average areal values applied to average or mean rainfall rates for large basins may yield results that are quite inadequate. He has given one of the limitations of the "average areal infiltration capacity"—namely, when a storm has rainfall rates over parts of the area less than the corresponding infiltration capacity, the computed value of average infiltration capacity for the entire area will always be less than the actual.

As suggested by Mr. Harrold in the example of Table 6, this can be avoided by applying infiltration-capacity curves to each sub-area precipitation diagram separately, thus obtaining Thiessen area-excess rainfall diagrams that can then be weighted and combined.

In a personal letter to the writers Mr. Horton has called attention to the fact that he has given[14] a general equation for the rising side of the hydrograph which is applicable to various types of flow:

$$q = \sigma \tanh^{M} \left[\frac{M + 1}{M} (\sigma K_s)^{(M-1)} t \right] \quad \ldots\ldots\ldots\ldots\ldots (21)$$

Eq. 4*a* follows directly by substitution of the value of $M = \frac{5}{3}$, which is that for fully turbulent flow in Eq. 21. The reader is referred to Mr. Horton's paper[14] for a development of the proper value of K_s for fully turbulent flow.

Mr. Sherman's comments supplement the paper and emphasize certain facts that were not sufficiently covered therein. His discussion of average infiltration capacity may not be clear to those readers who are not familiar with the *Proceedings* of the American Geophysical Union.

Mr. Sherman's calculation of "equivalent time T" for correlating the periods of observed rain intensities with the infiltration-capacity curves is based upon the same fundamental assumption as the method used by the writers—namely, that infiltration decreases with an increase in soil moisture. It may well develop out of further research and analysis that some simple method such as Mr. Sherman's will establish, adequately and practically, the initial value of the infiltration curve that is to be used at the beginning of each storm or of each of several separated parts of one great storm. As indicated by Mr. Musgrave, however, the variation in initial infiltration rates is not solely attributable to variation in soil moisture. It is to be hoped that out of the kind of research exemplified by Table 11 a clear enough picture of the mechanics of infiltration will evolve so that hydrologists may know what the dominant controls of initial capacities are, and accordingly can, with practical accuracy and economy of effort, quickly "position" the applicable infiltration-capacity curve at its correct initial point.

All this is not to deny that present methods are within the range of accuracy attainable by the older methods. The brief experience of several workers in this field indicates, for example, that Mr. Sherman's method of correlation is satisfactory.

It is to be regretted that, in the paper, space limitations caused the omission of some discussion of "average areal infiltration capacity," because the determination of "'average loss rate' (f_{av})" can be a useful approach. The value of "average areal infiltration capacity" does not, of course, represent the actual infiltration capacity of any part of the basin at any time. It is not related to any specific soil and cover combination, and therefore has no physical significance. It seems preferable not to refer to it as infiltration capacity at all, although it is an integration, through area and time, of real infiltration capacities during the storm period from which it is derived. Mr. Sherman's term "average loss rate" seems more truly descriptive.

A series of such values derived from storms occurring over the full range of seasonal variation in vegetal cover is usable in estimating flood flow from any pattern storm likely to occur in a particular season. The relationship developed is much superior to any involving a coefficient of runoff, or one based on total losses. Its major weakness lies in the assumptions involved in setting up rainfall patterns for non-recording stations, and in the common expression of such patterns in hourly values of uniform mean intensity. As shown elsewhere, such hourly mean values do not generally represent precipitation in the manner in which it actually occurs. For short storms, on small basins, the assumption of constant infiltration capacity throughout the storm period would introduce material errors, unless it is also assumed that the storm is immediately preceded by other heavy rainfall and that the infiltration-capacity value is that for the latter part of a total precipitation period.

The method has been presented by Mr. Horton and R. Van Vliet,[21] by Mr. Sherman,[22] and by Walter B. Langbein,[41] and it is to be hoped that a complete illustrative application will be published in the near future for the benefit of the profession.

It is the belief of the writers that where applicable values of actual infiltration capacity are available (as, for example, from small watersheds representative of the principal soil and cover combinations in the basin) the first method of determining excess rainfall using actual infiltration capacity will give more accurate results than one involving average areal values.

As pointed out by Mr. Flynt, the method is particularly applicable to airport and urban drainage—for example, in any instance where close control can be held over the physical factors, such as slope and nature of surfaces, and where the values involved justify a thorough analysis.

The most difficult step in the analysis of large areas can be the groundwater return to the flood hydrograph, but where this is not a problem the steps that Mr. Flynt has outlined for handling large areas are patently more realistic and representative of actual occurrence than any all-embracing coefficient, the choice of which involves an application of judgment possessed only by a relatively small group of highly specialized hydrologists; and, more importantly, the use of coefficients appears easy and hence can be dangerously abused.

Mr. Schafmayer's statement that the many variables involved in runoff determination emphasize "the bearing of chance events on any estimate of runoff rates or of the probable frequency of any particular rate" gives a pertinent reason why the deprecated "microscopic approach" is not only justified but virtually mandatory if those important variables capable of reasonably accurate determination are to accorded due emphasis.

Eq. 14 is not complete without the inclusion of a constant to express the ratio of the peak flow to the mass net rainfall; and, of course, such a "coefficient" must reflect, properly, the particular pattern of the collecting system.

Mr. Schafmayer's hope that Eqs. 15 and 16 will ultimately prevail is an understandable wish; but it is not readily apparent that experience, and analysis of the data coming out of that experience, will easily yield a variety of coefficients, runoff rates per square mile, or the like, which will adequately cover the multitude of varying combinations of surface, slope, vegetation or cover, soil, antecedent rainfall, stream pattern, and soil moisture—to mention only a few of the major variables. It is clear also that, unless the coefficient to be used does reflect the specific conditions being considered, its use is no more accurate than the statement that a certain person will die at the age of 65 because the average span of life, as accurately determined from a great mass of reliable data, is 65 yr.

---

[41] "Some Channel Storage Studies and Their Application to the Determination of Infiltration," by Walter B. Langbein, *Transactions*, Am. Geophysical Union, 1938, Pt. I, p. 435.

The writers cannot agree with Mr. Schafmayer in his statement that "since the objective of the designer is to determine the peak storm flow, the time factor, which is important in the rational method, loses its importance in the method proposed by the authors." The time of overland flow, the time for storage to be built up in the particular channel or pipe system, the time for disposition of the detention and channel storage through the recession side of the hydrograph, as well as the time for additional infiltration to take place during such recession, and the time of transit in various branch and trunk elements of the drainage system above the point being investigated are all of utmost importance.

The technique and mechanics involved in the paper seem to offer a tool of especial promise for a thorough reexamination of the current conception of critical time. As commonly stated under the rational theory, the maximum rate of runoff will be produced by a rain having a duration equal to the time of flow from the most remote point of the drainage area to the point under design. From a consideration of the hydrology of the rainfall curve, this hypothesis appears reasonable. From a consideration of the hydraulics of overland flow, as revealed by this demonstration, the conception of the time of transit needs complete reconsideration. For example, in the case of the 40-min uniform rain illustrated in Fig. 6(*a*), it is noticeable that, after the beginning of this "critical" rainfall, there is a period of time during which no surface runoff occurs from the pervious area; call this value t_0. Without, in the first instance, disturbing the theory of the critical time further, it would appear that this time should be at least t_0, plus the time of flow from the remote point of the area.

Further inspection of the hydrographs shows that at the end of this rainfall the rate of runoff from the pervious areas is still increasing rapidly. If the time of transit were developed from a consideration of velocities and lengths, and the velocities were those related to the very small depths existing at the beginning of overland flow, then the time of transit of the first overland flow produced at the extreme limit of the watershed would be quite long. If velocities were considered that were related to larger depths of detention at some indeterminate time after the beginning of overland flow, the time of transit would be less, but the point chosen as the beginning of the time of transit would be later on the hydrograph. From a consideration of velocity and length alone, it would appear that the beginning of overland flow should be taken at some time after the actual beginning and at a point on the rising side of the hydrograph of flow where the velocities would have material values.

When these hydraulic considerations are "brought into the picture," it would appear that the maximum rate of flow would result from a rain having a duration equal to t_0, plus a time t_1 necessary for the rate of overland flow to attain material values, plus a final item t_2 equivalent to the time of transit under these conditions. An actual application of these considerations to any particular rainfall curve and hydrograph would develop a critical time much greater than the current interpretations would indicate.

Finally, however, there is another important item to be considered. It is quite clear that the maximum rate of flow at the design point is not a matter of velocities and distances only, but results from the establishment of equilibrium out of the storage equation. For example, there is a storage lag involved that the foregoing procedure does not evaluate satisfactorily. It is entirely possible that a re-study along the foregoing lines will make it possible to retain the conception of critical time as a valuable index.

It should be further emphasized that the particular curves in the paper (Figs. 5, 6, 7, 12, 13, etc.) are valid only for the conditions from which they have been derived and in no sense should they be used directly for any area or block differing materially from the physical conditions and dimensions assumed.

Mr. Schafmayer comments on the "notable uniformity of peak flow for the 60-min, 40-min, and 20-min points whether the storm is of the advanced, intermediate, or delayed pattern." In studying the peak runoff rates displayed in Table 5, there are certain essential facts to be kept in mind. The first of these is that the results shown by Breihan's curve indicate, purely from a consideration of pattern occurrence, that within a rain of any particular duration there will be included; for periods of less duration, mean intensity precipitation approximately of the order of that which would exist for less duration under the normal rainfall curve. For example, within any one of these 60-min precipitation patterns there will be found a 40-min period for which the mean precipitation will be approximately the value that would be indicated for the 40-min period on the normal 5-yr rainfall curve; and similarly, within either the 60-min or 40-min patterns there will be found a 20-min period having a mean intensity approximately equal to that shown for 20 min on the 5-yr rainfall curve.

In general, the peak rates of flow that are shown in the table, as at manhole *A*, are responsive directly to the periods of high precipitation within the rainfall pattern. In other words, the peak occurring at this point as the result of the 60-min rain is largely influenced by the heaviest 10-min to 20-min precipitation within the 60-min rain.

From this background, it is not difficult to understand why the peak rates at the 20-min point should be higher for the longer storms. In other words, it is not surprising that the values shown in Table 5 appear to violate the criteria of the rational method. When it is remembered, however, that these longer rains also contain the critical shorter rains within them, and that, as a part of the longer rains, the critical shorter rains occur after infiltration rates are reduced and surface detention built up, the result appears to be entirely reasonable. Possibly the aforementioned violation of criteria is only a violation of a common misinterpretation of the criteria, in that hydrologists have been somewhat accustomed to think of these critical rains as isolated periods of precipitation not joined to other precipitation before or after the critical period. An inspection of the records on which any of the rainfall curves are based will show that such a case is the exception rather than the rule, and that the background of the average rainfall curve consists of sections taken out of longer rains and subjected to statistical analysis.

The second matter of importance in studying the values in Table 5 is a recognition that the introduction of patterns introduces a new frequency item. For example, it is imaginable that, of all the patterns in which a 60-min rain might occur, the uniform pattern is the one that practically never occurs; and that possibly one half of the occurrences are of the advanced type, and one quarter each are of the intermediate and delayed types. From this background, the peak runoff rate resulting from the advanced pattern based on a 5-yr rainfall curve would have a real frequency of the order of 10 yr, and the runoff rates resulting from the intermediate and delayed patterns of a similar 5-yr curve would have a real frequency of the order of 20 yr.

Such an analysis approaches the quantitative values in which the engineer is actually interested—the peak rates of flow that will have a specific frequency designation. The foregoing values are only a partial approach to a determination of the flow rates that may be expected with a particular frequency. A complete study of this matter would require a determination of flows under different rain patterns for mean rates taken from rainfall curves of several frequencies, and the undertaking of a new statistical analysis of all of the results to determine the true probability of a specific peak rate of flow for a particular physical situation.

One idea back of the preparation of this paper was that the engineers of one or more of the large cities might be stimulated to test out the suggested method in storm-drainage design. The writers are agreeably surprised to find that such work is already being done at Los Angeles, Calif. It is encouraging to them to learn that Mr. Hicks has arrived at much the same general principles for surface runoff determination through wholly independent studies. It is particularly significant that he too has discarded the unrealistic uniform rainfall pattern.

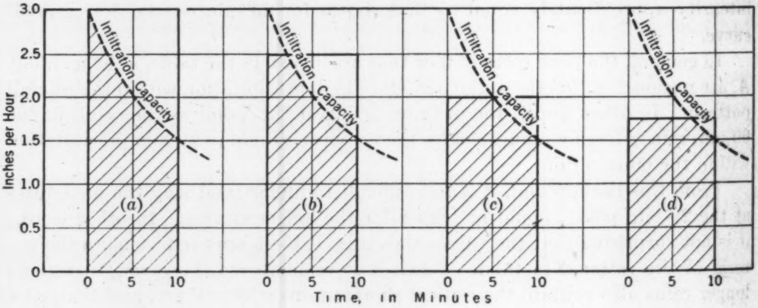

FIG. 19

Fig. 16 is the first experimental evidence that infiltration-capacity values are dependent upon rainfall intensity, and it is not clear from Mr. Hicks' explanation why this is so. That higher rainfall intensities will satisfy more quickly the interception requirements of the turf cover is plain, but that the infiltration capacity is increased because of "more complete coverage of the imperfect plane surface of urban yards" is not readily visualized. It is difficult to understand why higher intensities of precipitation should result in a more complete coverage; the prevailing concepts of surface detention and depression storage postulate runoff from an entire area only after complete coverage has been effected. In the absence of a clear knowledge of the derivation of the curves of Fig. 16, the writers nevertheless have speculated upon whether or not "loss rate," as given in Fig. 16, is identical in definition with infiltration capacity as used in the paper.

If the same infiltration-capacity curve is applied to each of four uniform rains of differing intensities, as shown in Figs. 19(*a*), 19(*b*), 19(*c*), and 19(*d*), it is plain that "loss rates" can be computed which substantiate Fig. 16. By dividing the shaded area in each instance (which represents the mass loss) by the elapsed time—in other words, obtaining the average ordinate for each shaded area—the following values (in inches per hour) result:

Case (Fig. 19)	Rainfall rate	Loss rate
a	3.1	2.10
b	2.5	2.02
c	2.0	1.87
d	1.75	1.69

For the sake of simplicity, all of these hypothetical rains are assumed to occur under identical antecedent conditions, thus placing the assumed infiltration-capacity curve at the same initial values. Fig. 20 is strikingly similar to the curves of Fig. 16; and, for any series of rainfalls each involving blocks at less than infiltration-capacity rates (as in the simplified example), it is obvious that the "loss rate" must vary with the intensity of rainfall.

Mr. Hicks' comment concerning the position of the impervious areas in the typical lot is correct: In the actual urban lot some appreciable part of the impervious area drains on to turf before its flow reaches the street or alley. In the writers' example, the primary purpose was to illustrate the principles involved, and the disposition of the component areas of the typical lot was chosen in part to illustrate the conditions that would contribute the greatest runoff and in part to facilitate the mechanics of evaluating the various contributions.

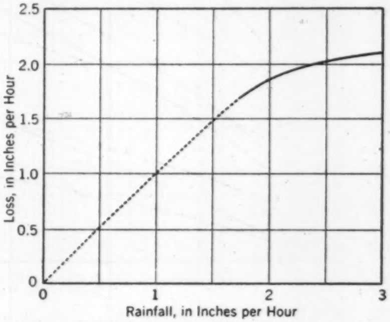

FIG. 20.—RAINFALL RATE-LOSS RATE CURVE

The exponential formulas derived from the experiments reported by Mr. Hicks are strikingly similar in form to Mr. Horton's equations for depth of detention. If Eq. 3*b* is assumed to have the hyperbolic tangent equivalent to unity (which is the case for equilibrium flow), the slope is expressed in percentage, and the result multiplied by $\frac{2}{3}$ to express mean depth of detention:

$$\delta_a = \frac{0.036\, l^{0.5}\, \sigma^{0.5}}{S^{0.25}{}_0} \qquad (22)$$

The constant in Eq. 22 is based upon experimental values reported in 1938,[12] and it is approximately half that of Eq. 19*a*. The larger constant, however, was obtained from clipped sod, whereas the lesser figure resulted from tests on uncut pasture grass of undoubtedly lesser density. The exponents also reflect a difference in the character of flow over the two surfaces. For example, the exponents of Eq. 3*b* are assumptions of 75% turbulent flow, whereas Eq. 19*a* indicates a lesser percentage of turbulence. It seems probable that the exponents and constant of Eq. 19*a* reflect more accurately city lawn conditions than do those used in the paper. Fig. 21 illustrates the influence of the constants and exponents over a range of supply rates for two lengths and slopes.

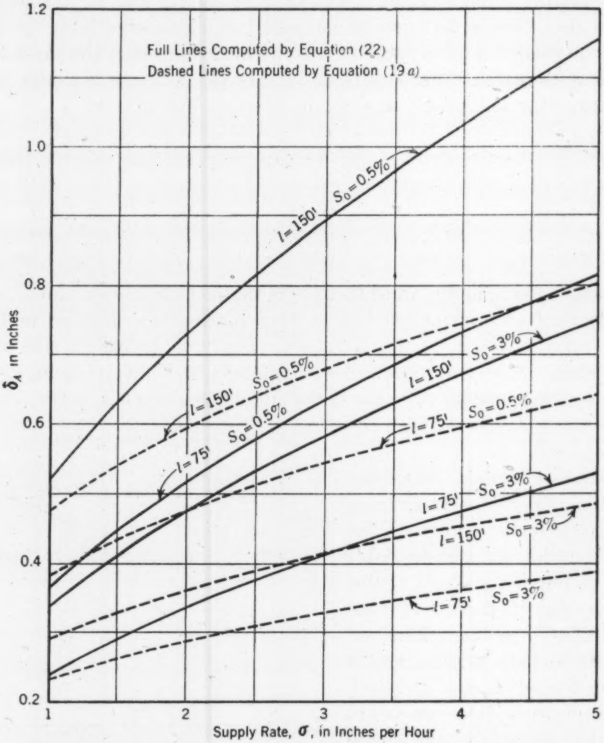

FIG. 21.—COMPUTATION OF δ_a-CURVES BY EQS. 19*a* AND 22

It is clear that the greater exponents in the denominator of Eq. 22 overshadow the lesser constant. The clipped sod appears to develop less detention storage than does the uncut pasture grass. Fig. 21 also shows the considerably greater detention storage built up for the flatter slopes and longer overland flow lengths.

Fig. 18 seems to postulate the theory that time of concentration is that time at which all the surface detention and all the channel storage above the point being studied have been developed or are being utilized; and, from Eq. 20*a*, it appears that Mr. Hicks has evaluated gutter storage in terms of equivalent average depth of flow in the gutter. The symbol "*l*" in Eq. 20*a* is length of gutter.

With reference to Mr. Hicks' comments concerning the summation of the block hydrographs, admittedly there is a danger of accumulative error, but the basic procedure is believed to have the decided advantage of simulating realistically the actual building up of flow as it progresses downstream. It should be noted that for closed systems (such as pipes or large conduits), the hydraulics of the flood wave will not enter the problem, if as is usual the analysis is confined to examination of peak flows. A properly proportioned closed system will flow full or under head when carrying the design flow, and the flood wave obviously cannot exist.

Mr. Hicks has stated in a letter to the writers that the fifth paragraph following Eqs. 12 "seems to indicate that a hydrograph of short duration is not reduced as much by gutter storage as the broader hydrographs for a 40-minute rain." It is regretted that any ambiguity should have arisen, because the work graphs (which could not be reproduced due to space limitations) and tables do show that the gutter storage does have a considerably greater reducing effect for the shorter, more intense rains. The relative effects of surface detention and of gutter channel storage are not evident in the graphs of Figs. 5, 6, and 7; their combined effect is indicated by the difference between the "Supply Rate for Block" and "Outflow Hydrograph for Entire Block."

It is to be earnestly hoped that Mr. Hicks will publish a full report on the commendable hydrologic research at Los Angeles so that all of the data and his interesting analysis and methodology may be available to engineers and hydrologists.

MOMENTS IN CONTINUOUS RECTANGULAR SLABS ON RIGID SUPPORTS

BY L. C. MAUGH,[1] ASSOC. M. AM. SOC. C. E., AND C. W. PAN,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. MAURICE P. VAN BUREN, RALPH E. BYRNE, JR., PIERCE P. FURBER, AND L. C. MAUGH.

SYNOPSIS

A method of analysis for rectangular slabs, supported on four sides and continuous over the supports, is described in this paper. The solution is so arranged that the equations providing continuity between the panels can be expressed in terms of the restraining moment at the middle of each support. The computations are simplified by using a sine distribution for the edge moments and by establishing continuity between the panels only at the middle of the supports. These approximations enable the solution to be based on assumptions that more nearly represent the fundamental structural action than does the use of hypothetical beam strips. Diagrams are provided from which the equations can be expressed easily. These equations are solved most conveniently by successive approximations.

INTRODUCTION

The moments, shears, and deflections in a single rectangular panel, either simply supported or fixed at the edges, have been computed for many types of loading. When a floor slab is continuous over the supports in all directions, an exact mathematical solution is possible but time-consuming, as the behavior in any panel then varies with the loading and physical characteristics of contiguous panels. Along with this action, the vertical deflection and torsional stiffness of the supporting beams provide additional disturbing factors. Confronted with these difficulties, the engineers who have developed the various building codes have naturally emphasized the most obvious action of the slab—that is, the flexure of the member in its two principal directions.[3] When the slab is simply supported, this flexural action is apparent, and the selection of

two orthogonal strips, such as *AB* and *CD*, Fig. 1(*a*), that are considered as simply supported beams is a natural approximation. The distribution of the applied loading to these strips is an indeterminate problem that is frequently solved by making the deflections of the strips equal at their intersection. Ordinarily such assumptions give safe results for the maximum bending moments at the center of the slab, as the torsional resistance of the slab is entirely neglected. By referring to Fig. 1(*b*), it can be seen that the twisting moments T_3 and T_4 on an element of the slab can assist in the transfer of the vertical load to the support along the strip *CD* and thereby reduce the bending moments M_1 and M_2. In the same manner, the twisting moments T_1 and T_2, Fig. 1(*c*), can reduce the bending moments M_3 and M_4 in any strip *AB*.

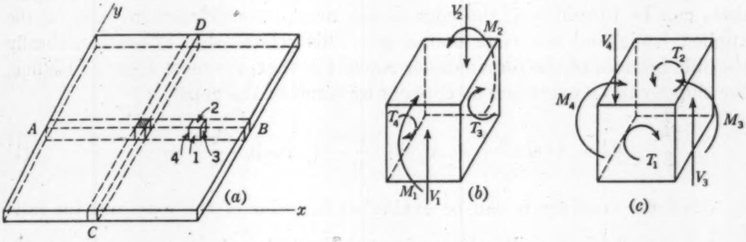

FIG. 1.—COUPLES ACTING ON AN ELEMENT OF A SLAB

In some building codes, such as the German Building Regulations, this reduction in the bending moments due to the torsional stiffness of the slab is effected by multiplying the moments that are obtained from an analysis of the individual strips by a reduction factor (Marcus approximation) that has been obtained from a slab analysis.[4] The present American Concrete Institute (A. C. I.) building regulations[3] in the United States also adhere to the use of individual strips that are considered as continuous beams in the case of continuous floor slabs. In this case, the only correction for the slab action is made by an empirical distribution of the load between the two hypothetical beams. In such analyses, continuity of strain throughout the slab is provided as a secondary factor, if at all, rather than as a fundamental part of the solution. The only alternative to the strip method appears to be in the direction of using the entire panel as a structural unit.

The use of the entire panel was adopted by Nathan M. Newmark, Assoc. M. Am. Soc. C. E., in his analysis of slabs that are continuous in one direction and simply supported on the edges parallel to this direction.[5] In that problem, where only two edges of any panel are subjected to bending moments, numerical tabulation of edge moments and of the corrections for edge rotations is feasible and can be applied directly. On the other hand, when slabs are continuous in all directions, there is considerable advantage in an algebraic arrangement that enables the conditions of continuity to be expressed by equations of standard form. Successive approximations then can be used in the numerical solution of these equations. This procedure was used by Prof. S. Timoshenko in his solution of a rectangular panel with fixed edges.[6]

[4] "Die Theorie elastischer Gewebe und ihre Anwendung auf die Berechnung biegsamer Platten," by H. Marcus, Berlin, Springer, 1932, p. 89.

[5] "A Distribution Procedure for the Analysis of Slabs Continuous Over Flexible Beams," by Nathan M. Newmark, *Bulletin No. 304*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill., 1938.

Regardless of whether an algebraic or direct arithmetical form of arrangement is used, the solution requires that the edge slopes of the elastic curve of the slab be expressed as the sum of the slope in a simply supported slab due to the applied loading, plus the slopes due to the restraining moments at the four edges. In the case of fixed edges, the resultant slope must be zero, but for continuous slabs the resultant slope in one panel must be equal and opposite to the resultant slope of the same edge in the adjacent panel. It should be noted that the foregoing procedure calls for satisfying the continuity conditions entirely around the boundaries of the various panels. Also, before the equations can be formulated, the edge slopes must be expressed in terms of the applied loads and the edge moments. This relationship is mathematically possible because of the fortunate circumstance that, for most types of loading, the slopes can be expressed as converging series of the type[7]

$$\theta_y = A_1 \sin \frac{\pi x}{a} + A_2 \sin \frac{2 \pi x}{a} + A_3 \sin \frac{3 \pi x}{a} + \cdots \qquad (1)$$

in which the coefficients can be evaluated in terms of the load and the ratio $\frac{b}{a}$, or $\frac{a}{b}$, which involves the dimensions of the slab. An exact solution is obtained if the first terms of each series are made to satisfy the required slope condition, then the second terms, then the third terms, etc. The actual edge moments will be the algebraic sum of the moments that satisfy the separate terms of the series. For instance, if the slopes along the boundary *AD* of the simply supported panel *ABCD*, Fig. 2(*a*), are considered, the rotation θ_y' at any distance x from the origin A, for a uniform load p per unit area over the entire panel, when $\frac{b}{a} = 1.0$, is equal to

$$\theta_y' = \frac{p a^3}{D}\left(0.0137 \sin \frac{\pi x}{a} + 0.00025 \sin \frac{3 \pi x}{a} + 0.000033 \sin \frac{5 \pi x}{a} + \cdots \right) \qquad (2a)$$

and, when $\frac{b}{a} = 1.5$:

$$\theta_y' = \frac{p a^3}{D}\left(0.0184 \sin \frac{\pi x}{a} + 0.00025 \sin \frac{3 \pi x}{a} + 0.000033 \sin \frac{5 \pi x}{a} + \cdots \right) \qquad (2b)$$

In all such equations the term D is used to represent the flexural resistance of the slab and is equal to

[6] "Bending of Rectangular Plates with Clamped Edges," by S. Timoshenko, *Proceedings*, Fifth International Cong. for Applied Mechanics, 1938.

[7] "Theory of Plates and Shells," by S. Timoshenko, McGraw-Hill Book Co., Inc., 1940, Chapters 5 and 6.

$$D = \frac{E\,h^3}{12\,(1 - \mu^2)} \ldots\ldots.(3)$$

in which h is the thickness of the slab and μ equals Poisson's ratio. The restraining moments along any boundary, such as AD, Fig. 2(b), can be represented by a corresponding sine series, as

$$M_y = M_1' \sin\frac{\pi\,x}{a} + M''' \sin\frac{3\,\pi\,x}{a} + M''''' \sin\frac{5\,\pi\,x}{a} + \cdots\ldots(4)$$

For this distribution of moments, the slopes along any edge also can be expressed as a sine series, thus, when $\frac{b}{a} = 1.0$:

$$\theta_y'' = \frac{a}{D}\left(0.156\,M' \sin\frac{\pi\,x}{a} + 0.053\,M''' \sin\frac{3\,\pi\,x}{a} + 0.0318\,M''''' \sin\frac{5\,\pi\,x}{a} + \cdots\right).(5a)$$

and, when $\frac{b}{a} = 1.5$:

$$\theta_y'' = \frac{a}{D}\left(0.159 \sin\frac{\pi\,x}{a} + 0.053\,M''' \sin\frac{3\,\pi\,x}{a} + 0.0318\,M''''' \sin\frac{5\,\pi\,x}{a} + \cdots\right).(5b)$$

If the edge AD is fixed while the others are simply supported, $\theta_y' + \theta_y''$ must be equal to zero for all points along the boundary AD. This condition can be realized if each term of the series for θ_y' is made equal but with opposite sign to the corresponding term of θ_y''. Thus, using Eqs. 2a and 5a, for θ_y' and θ_y'', when $\frac{b}{a} = 1.0$: For $\sin\frac{\pi\,x}{a}$,

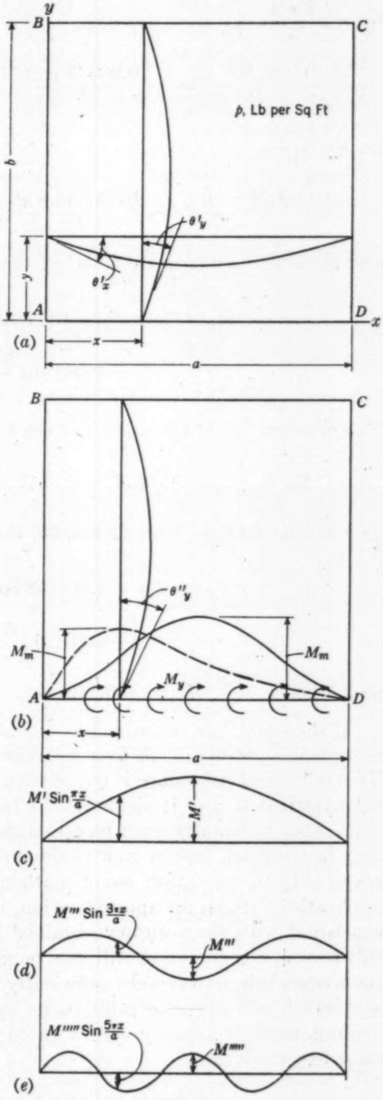

FIG. 2.

$$\frac{0.156\,M'\,a}{D} = -\,\frac{0.0137\,p\,a^3}{D}; \quad \text{or,} \quad M' = -\,0.0877\,p\,a^2$$

for $\sin \frac{3\pi x}{a}$,

$$\frac{0.053\, M'''\, a}{D} = -\frac{0.00025\, p\, a^3}{D}; \qquad \text{or,} \qquad M''' = -0.0047\, p\, a^2$$

for $\sin \frac{5\pi x}{a}$,

$$\frac{0.0318\, M'''''\, a}{D} = -\frac{0.000033\, p\, a^3}{D}; \qquad \text{or,} \qquad M''''' = -0.0010\, p\, a^2$$

and the edge moments are given by the series:

$$M_y = -p\, a^2 \left(0.0877 \sin \frac{\pi x}{a} + 0.0047 \sin \frac{3\pi x}{a} + 0.001 \sin \frac{5\pi x}{a} + \cdots \right) \ldots\ldots (6a)$$

The moment M_a at the middle of the edge, when $x = \frac{a}{2}$, will be

$$M_a = -p\, a^2 (0.0877 - 0.0047 + 0.001 + \cdots) = -0.084\, p\, a^2 \ldots (6b)$$

In a similar manner, Eqs. 2*b* and 5*b*, the corresponding series for $\frac{b}{a} = 1.5$, give

$$M_y = -p\, a^2 \left(0.1158 \sin \frac{\pi x}{a} + 0.0047 \sin \frac{3\pi x}{a} + 0.001 \sin \frac{5\pi x}{a} + \cdots \right) \ldots\ldots (7)$$

and, when $x = \frac{a}{2}$, $M_a = -0.112\, p\, a^2$.

If the panels are restrained on all sides, the slopes on the four sides must be expressed in terms of all four restraining moments and the applied loading. This numerical procedure is not particularly difficult when only one panel is to be investigated, and it yields results that are mathematically correct. However, when continuity must be established between several panels, all of which may be irregular, and in view of the uncertainties of the assumptions, it seems reasonable to relinquish some mathematical exactness for more facility of application. Such an approximation, of course, should give results that are consistent with the accuracy obtained in the average design procedure. For this reason, consideration will now be given to an approximate solution which the writers believe will yield sufficiently accurate results for average conditions and which will be practicable in its application. Any unusual condition of loading, such as a heavy concentrated load near one corner, will require the more exact solution.

APPROXIMATE METHOD OF SOLUTION

The distribution of the restraining moments along any support of a continuous floor slab may be either asymmetrical, as shown by the dotted line for side AD, Fig. 2(b), or symmetrical, as shown by the solid line. For many practical conditions of loading, the maximum value M_m will not vary greatly from the value M' (Fig. 2(c)) for a distribution of $M' \sin \frac{\pi x}{a}$, although the actual distribution is somewhat different. The type of loading best suited for such an approximation will naturally be one that is fairly symmetrical about the center of the panel, such as a uniform load over the entire panel or concentrated loads near the center. Unusual conditions, such as heavy concentrated loads near a support, will ordinarily be critical with respect to shear and, therefore, will require special consideration.

To simplify the numerical solution further, continuity between the various panels will be maintained only at the middle of each edge instead of entirely around the boundaries of each panel, as for the exact method. For any continuous slab, such as that in Fig. 3, the edge moments can be expressed in terms of the center moments $M_{12} = M_{21}$, $M_{15} = M_{51}$, etc., and continuity between the various panels is obtained by equating the slopes at the middle of each edge, as $\theta_{12} + \theta_{21} = 0$, $\theta_{15} + \theta_{51} = 0$, etc. Because of the fact that the distribution of moments along all edges is regarded as a sine curve, the slopes can be expressed directly in terms of the edge moments and the applied loading, as for a continuous beam on rigid supports. Thus, in Fig. 4, the angles α, β, and γ are given in terms of the moment $M' \sin \frac{\pi x}{a}$ for various values of $\frac{b}{a}$. Therefore, any edge slope such as θ_{12}, Fig. 3, can be expressed in the form

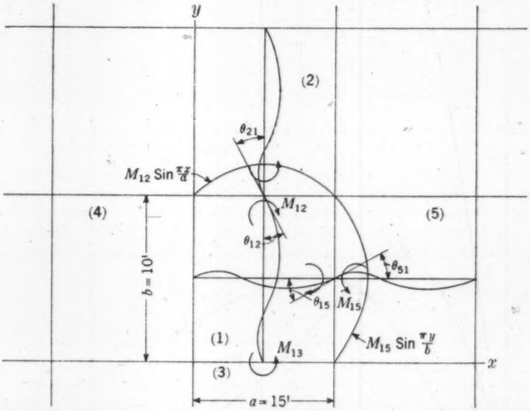

FIG. 3.—MOMENTS AND SLOPES USED IN THE APPROXIMATE METHOD

$$\theta_{12} = \alpha \left(\frac{M_{12}\, a}{D} \right) + \beta \left(\frac{M_{13}\, a}{D} \right) + \gamma \left[\frac{(M_{14} + M_{15})\, b}{D} \right] + \phi_s \ldots\ldots (8)$$

in which ϕ_s is the slope in a simply supported slab for the applied loading. Values of ϕ_s are given in Fig. 5(a) for a uniform load p per unit area over the entire panel, for a concentrated load P at the center of the panel, and, in Fig. 5(b), for a line load L across the center of the panel. It should be noted that, to determine the value of θ for a particular edge, the angles α and β are obtained by taking a as the length of that side, whereas for selecting γ the values of b and a are interchanged.

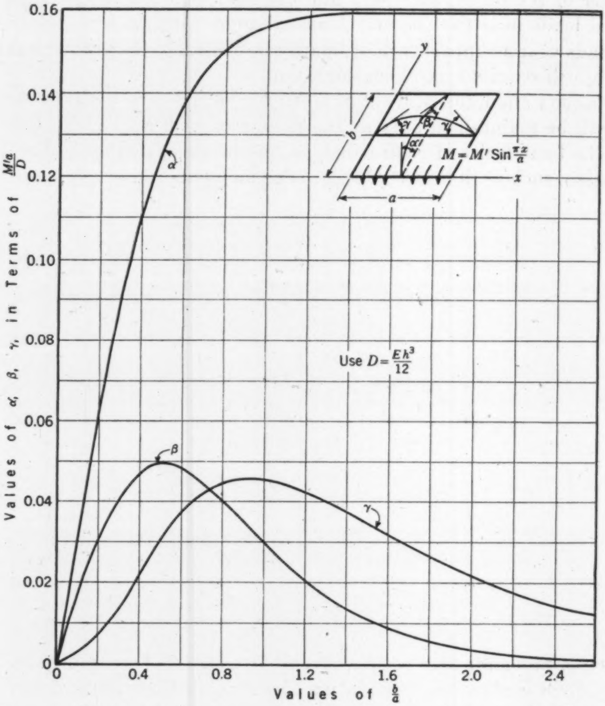

FIG. 4.—EDGE SLOPES α, β, AND γ IN A SIMPLY SUPPORTED SLAB DUE TO MOMENTS APPLIED ALONG ONE SIDE

To illustrate the use of the foregoing values, the equation for θ_{12} in panel (1), Fig. 3, will be given for a uniform load p over the entire area. For selecting α, β, and ϕ_s, $\frac{b}{a} = \frac{10}{15} = 0.67$; and, for selecting γ, $\frac{b}{a} = \frac{15}{10} = 1.5$. By Figs. 4 and 5($a$):

$$\theta_{12} = 0.143 \left(\frac{15\, M_{12}}{D} \right) + 0.046 \left(\frac{15\, M_{13}}{D} \right) + 0.035 \times 10 \left(\frac{M_{14} + M_{15}}{D} \right) + 0.0077 \times 15^3 \frac{p}{D} \quad \ldots\ldots\ldots (9)$$

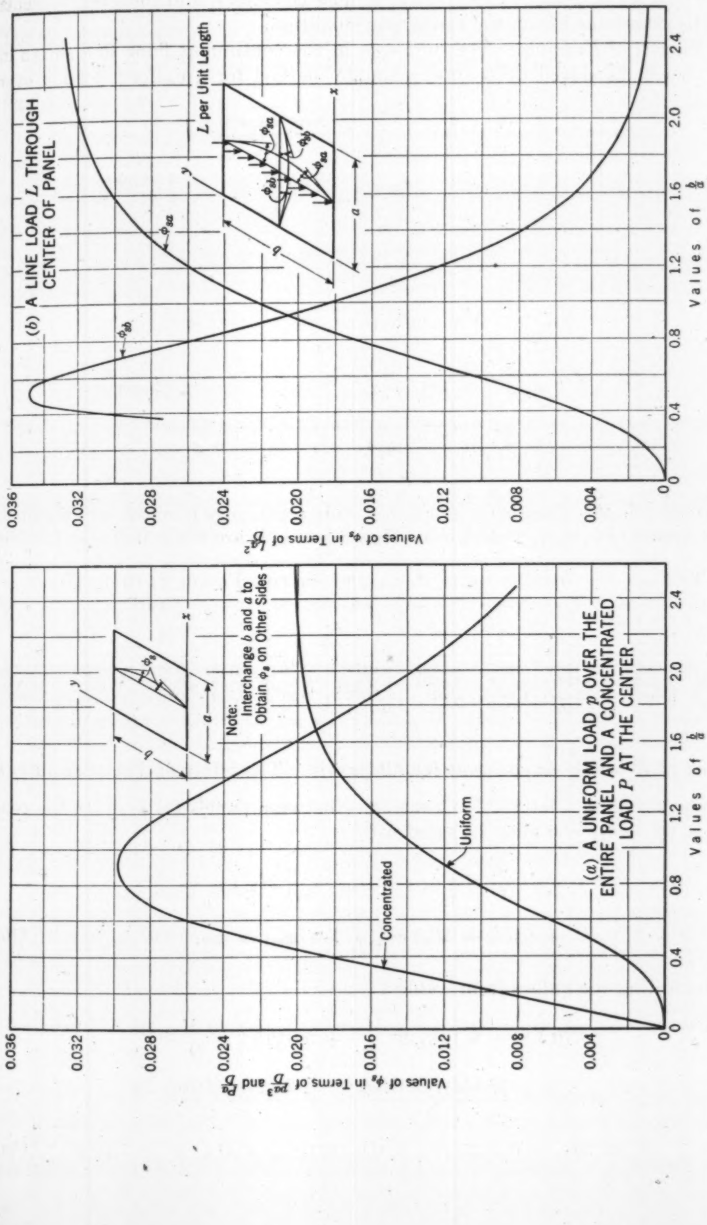

FIG. 5.—EDGE SLOPES ϕ_s

Other values of θ can be expressed by similar equations, and the edge moments can be determined from the continuity condition.

Numerical Example.—The moments in the continuous floor slab shown in Fig. 6 will be solved by the approximate method for a uniform load p over the entire floor. Because of symmetry, only seven edge moments are required. The values of α, β, γ, and ϕ_s from Figs. 4 and 5(a) are listed in Table 1. The value of $D = \frac{E\,h^3}{12}$ is constant for all panels. The effect of Poisson's ratio n will be considered later. For continuity between panels (1) and (2), the condition $\theta_{12} + \theta_{21} = 0$ must be satisfied:

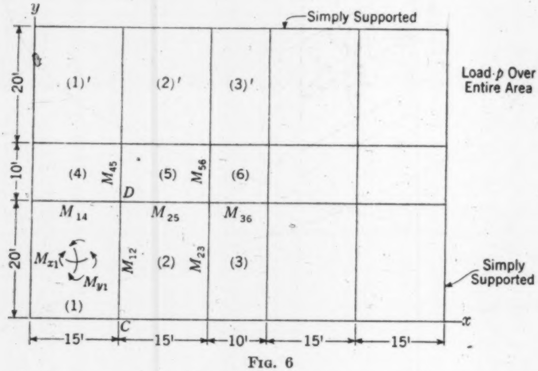

FIG. 6

TABLE 1.—VALUES OF α, β, γ, AND ϕ_s FOR FLOOR SLAB IN FIG. 6

Panel No.	$\frac{b}{a}$	α	β	γ	ϕ_s	$\frac{b}{a}$	α	β	γ	ϕ_s
1, 2	1.33	0.1583	0.0153	0.0395	0.0171	0.75	0.148	0.0425	0.0435	0.00925
3	0.5	0.126	0.049	0.0306	0.00425	2.0	0.159	0.003	0.0215	0.0198
4, 5	0.67	0.143	0.046	0.041	0.0077	1.50	0.159	0.011	0.035	0.0182
6	1.0	0.156	0.030	0.045	0.0134	....	....	....	....	....

$$\frac{a}{D} M_{12} (\alpha_{12} + \alpha_{21}) + \frac{a}{D} M_{23} \beta_{21}$$

$$+ (M_{14} + M_{25}) \gamma \left(\frac{b}{D}\right) + \phi_{s12} + \phi_{s21} = 0 \ldots\ldots\ldots\ldots (10)$$

Substituting the values from Table 1:

$$(0.148 + 0.148)\, 20 \frac{M_{12}}{D} + 0.0425 \left(\frac{20\, M_{23}}{D}\right)$$

$$+ 0.0395 \frac{15\,(M_{14} + M_{25})}{D} = - \frac{2 \times 0.00925\, p\, 20^3}{D};$$

or,

$$0.296\, M_{12} + 0.0425\, M_{23} + 0.0295\, (M_{14} + M_{25}) = - 7.40\, p \ldots (11a)$$

In a similar manner, the following equations can be obtained:

For $\theta_{23} + \theta_{32} = 0$—

$$0.0425\ M_{12} + 0.3239\ M_{23} + 0.0295\ M_{25} + 0.0107\ M_{36} = -\ 5.324\ p \qquad (11b)$$

for $\theta_{45} + \theta_{54} = 0$—

$$0.318\ M_{45} + 0.0107\ M_{56} + 0.1213\ (M_{14} + M_{25}) = -\ 3.64\ p \qquad (11c)$$

for $\theta_{56} + \theta_{65} = 0$—

$$0.0107\ M_{45} + 0.3448\ M_{56} + 0.1213\ M_{25} + 0.0914\ M_{36} = -\ 3.16\ p \qquad (11d)$$

for $\theta_{14} + \theta_{41} = 0$—

$$0.3478\ M_{14} + 0.0580\ M_{12} + 0.0230\ M_{45} = -\ 5.55\ p \qquad (11e)$$

for $\theta_{25} + \theta_{52} = 0$—

$$0.3478\ M_{25} + 0.0580\ (M_{12} + M_{23}) + 0.0230\ (M_{45} + M_{56}) = -\ 5.55\ p \qquad (11f)$$

and for $\theta_{36} + \theta_{63} = 0$—

$$0.3449\ M_{36} + 0.1238\ M_{23} + 0.0914\ M_{56} = -\ 3.321\ p \qquad (11g)$$

Eqs. 11 can be solved conveniently with a slide rule by the method of iteration. If approximate values of the larger moments are first obtained, the entire set of moments can be tabulated quickly. The numerical values of these moments, together with the corresponding values of the same moments that are given by the exact method and by the A. C. I. Code, are given in Table 2.

TABLE 2.—EDGE MOMENTS AT MIDDLE OF SUPPORTS, IN TERMS OF p, FOR FLOOR SLAB IN FIG. 6

The distribution of edge moments along the support CD between panels (1) and (2) (Fig. 6) is shown in Fig. 7 for the exact method, together with the distribution that is obtained by the approximate method. It can be seen that the maximum ordinate for the exact distribution is near the center and is practically equal to the maximum ordinate of the assumed sine curve.

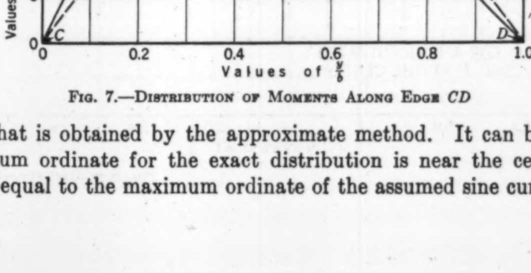

FIG. 7.—DISTRIBUTION OF MOMENTS ALONG EDGE CD

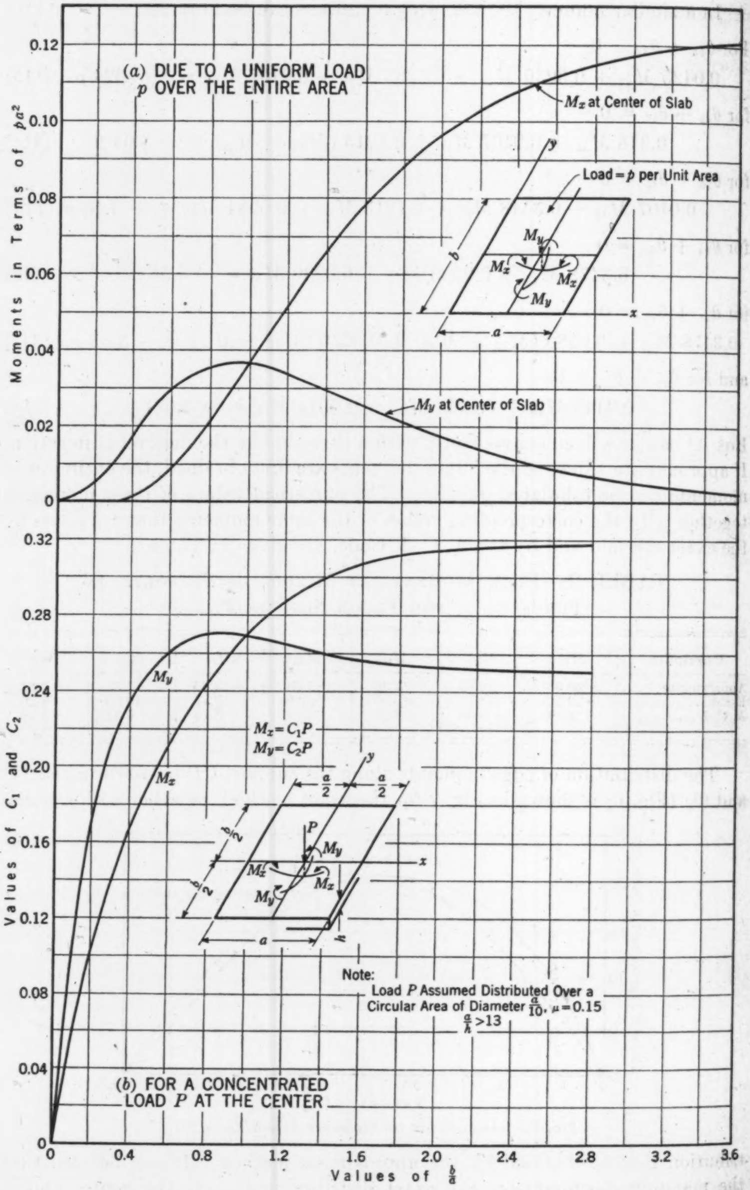

FIG. 8.—MOMENTS AT THE CENTER

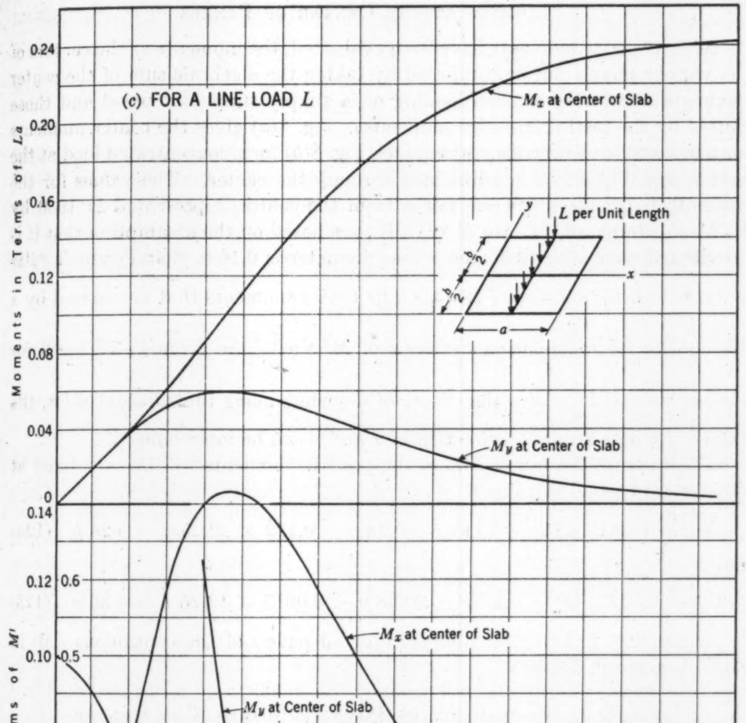

OF A SIMPLY SUPPORTED SLAB

Moments at the Center of Panels

After the edge moments have been evaluated, the moments at the centers of the various panels can be computed by taking the algebraic sum of the center moments due to the applied loading on a simply supported panel and those caused by the restraining edge moments. Fig. 8(*a*) gives the center moments for a uniform load over the entire panel, Fig. 8(*b*) for a concentrated load at the center, and Fig. 8(*c*) for a line load through the center. The values for the concentrated load, which are taken from the solution[8] presented in 1930 by H. M. Westergaard, M. Am. Soc. C. E., are based on the assumption that it is distributed over a circular area whose diameter is 0.10 a, that Poisson's ratio is equal to 0.15, and that $\frac{a}{h} > 13$. The center moments that are caused by a distribution of moments alongside a of $M' \sin \frac{\pi x}{a}$ are given in Fig. 8(*d*) for various values of $\frac{b}{a}$. For the effects of moments along the adjacent sides, the values of a and b and the direction of x and y can be interchanged.

To illustrate the use of Fig. 8, the positive moments will be calculated at the center of panel (1), Fig. 6:

$$M_{x1} = 0.0618\, p\, 15^2 - 0.144 \times 20.98\, p - 0.132 \times 12.25\, p = 9.28\, p \quad \text{(12a)}$$

and

$$M_{y1} = 0.032\, p\, 15^2 - 0.1365 \times 20.98\, p - 0.0015 \times 12.25\, p = 4.36\, p \quad \text{(12b)}$$

A comparison of the center moments for all panels of the continuous slab in Fig. 6 is given in Table 3.

TABLE 3.—Comparison of Positive Moments at Center of Panels for Slab in Fig. 6, in Terms of p

$\mu = 0.2$	10.15	6.22	8.48	4.19	1.88	−0.56	+0.24	2.43	0.99	2.95	2.46	2.34
Exact Method; $\mu = 0$	9.34	4.27	7.88	2.72	1.98	−0.76	−0.27	2.38	0.35	2.84	2.06	1.83
A. C. I.	7.21	6.16	5.94	4.13	2.30	1.55	1.72	−0.06	1.81	0.84	1.28	1.10

In the foregoing analysis, Poisson's ratio μ has been taken equal to zero. This assumption has little effect upon the edge moments, but the positive moments may be affected considerably. However, when the positive moments are known for $\mu = 0$, they can be computed for any other value of μ from the relations:

$$M_x = M_x' + \mu\, M_y' \quad \text{(13a)}$$

and

$$M_y = \mu\, M_x' + M_y' \quad \text{(13b)}$$

in which M_x' and M_y' are the values for $\mu = 0$. For instance, the positive moments in panel (1), Fig. 6, for $\mu = 0.2$, are:

---

[8] "Computation of Stresses in Bridge Slabs Due to Wheel Loads," by H. M. Westergaard, *Public Roads*, Bureau of Public Roads, U. S. Dept. of Agriculture, Vol. II, No. 1, 1930.

$$M_{x1} = 9.28\,p + 0.2 \times 4.36\,p = 10.15\,p \qquad (14a)$$

and

$$M_{y1} = 0.2 \times 9.28\,p + 4.36\,p = 6.22\,p \qquad (14b)$$

This change in the value of μ produces an increase in the center moments of 9.4% and 42.6%, which indicates that some consideration should be given to this factor. All diagrams in this paper are for $\mu = 0$, except Fig. 8(*b*), which is based on $\mu = 0.15$. If the moments M_x and M_y are known for any value of μ, the values of M_x' and M_y' for $\mu = 0$ can also be determined by Eqs. 13.

CONCLUSION

From the numerical examples that are given in the paper, together with many others that are not recorded herein, the following conclusions appear warranted:

(*a*) The solution of continuous rectangular slabs can be made more accurately by treating the entire panel as a structural unit than by analyzing individual strips as continuous beams.

(*b*) The use of an approximate method which assumes that the edge moments are distributed according to a sine curve, and which provides continuity at the middle of each edge, is feasible and gives maximum positive negative moments with sufficient accuracy for average loading conditions on any panel. Unusual loading conditions have not been considered.

(*c*) The equations that are used can be solved quickly by the method of iteration with the aid of an ordinary slide rule. Various loading conditions can be investigated by changing the constant term in each equation.

(*d*) The only apparent alternative to the foregoing approximate method appears to be in the development of tables of values for positive and negative moments for various panel arrangements and various ratios of live to dead load. Such a compilation of values by an exact method would be a long and laborious procedure; but it is possible with the aid of the curves and equations now available.

ACKNOWLEDGMENT

Most of the numerical data and diagrams in this paper have been taken from a dissertation by C. W. Pan on the "Analysis of Continuous Slabs," submitted in April, 1939, in partial fulfilment of the requirements for the Degree of Doctor of Science at the University of Michigan, Ann Arbor, Mich.

DISCUSSION

Maurice P. van Buren,[9] Assoc. M. Am. Soc. C. E.—A simplified method of analysis for slabs supported on four sides is contained in this interesting paper. By the assumption that edge slopes and support moments are distributed according to a sine curve, formulas for moments at any point are obtained. Unfortunately, the derivations of Eqs. 2 and 5 are not given, and it is not clear what fundamental relationships connecting slope, load, and moment were used by the authors in their analysis, or whether the effect of torsional rotation has been included. It is to be hoped that this omission will be remedied in the closing discussion.

Values given in the text for support moments in slabs fixed at one edge, and the curves in Fig. 8(*a*) for positive moments in simply supported slabs, agree closely with the theoretical values obtained from elastic analysis using Fourier series by H. M. Westergaard,[10] M. Am. Soc. C. E., in 1921; but it should be pointed out that, in the long direction of oblong panels, the moment M_y (Fig. 8(*a*)) at the center of span may be less than the theoretical maximum. For example, when the ratio of spans is 2, maximum moments occur at about the 0.3 point of the span from each end with a depression of the moment curve at midspan. However, in 1926, Dean Westergaard further modified his formulas[11] to agree with tests by taking into account redistribution of stress. As the load on a panel is gradually increased from zero, bending moments will increase more rapidly in the stiffer parts of the slab than in the more flexible parts. This involves a transfer of bending moment from the center strips to the side strips with a consequent flattening out of the curve of moment distribution across the panel width. During this action there also may be a change in the proportion of load carried by each direction of the slab, and also to some extent a transfer of moment from the support to the center of span. Dean Westergaard's conclusions indicated a reduction in maximum bending moments due to redistribution of 28%. From these considerations it follows that, although a sine-curve distribution may portray conditions satisfactorily at the beginning of the loading, it does not represent the true conditions in the later stages and yields moments considerably too high for purposes of design.

As one of the authors of the A. C. I. regulations for slabs supported on four sides,[12] the writer wishes to correct the impression that these provisions are merely a beam strip method in which "the only correction for the slab action is made by an empirical distribution of the load between the two hypothetical beams" (see "Introduction"). A brief description of the basis of the A. C. I. formulas will be given. This method of analysis is devised for practical use, and simplifying approximations and empirical constants are introduced within the limits of required accuracy without sacrificing the rational form of the equations. Under the A. C. I. regulations, consideration is given to the action of the entire panel as a unit, and the proportion of the total panel load to be carried in each direction is determined by the relative stiffness of the two spans. The distances between lines of inflection when uniform load is applied separately to each span form convenient measures of the relative stiffness of the two directions. For a panel $A \times B$, this results in a load distribution formula:

[10] "Moments and Stresses in Slabs," by H. M. Westergaard and W. A. Slater, *Proceedings*, A. C. I., 1921, p. 415.

[11] "Formulas for the Design of Rectangular Floor Slabs and the Supporting Girders," by H. M. Westergaard, *loc. cit.*, 1926, p. 26.

[12] "Slabs Supported on Four Sides," by J. Di Stasio and M. P. van Buren, *loc. cit.*, 1936, p. 350.

$$r_A = \frac{1}{1 + \left(\frac{F_A\,A}{F_B\,B}\right)^3} = 1 - r_B \quad\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which r_A and r_B are the proportions of total panel load carried in each direction, and $F_A\,A$ and $F_B\,B$ are distances between lines of inflection as defined above. The factors $F_A\,A$ and $F_B\,B$ have small variation for usual conditions, and the effect of loads on adjacent panels should be neglected in their determination. It is to be noted that Eq. 15 is not the fourth power distribution, based on the deflections of two intersecting center strips commonly used in the "beam strip" methods, but is a third power distribution that implies the equality of deflections in each span at all corresponding points in the panel.

In addition to distributing the total load between the two directions of the panel, the variation in intensity of loading along each span is also provided for. For instance, at the center point of a square symmetrical panel, one half the unit load is carried in each direction, but, at a point near a support, practically all of the unit load goes directly to the support. Load distribution coefficients are therefore modified by equivalent uniform load factors:

$$e_A = \frac{2}{4 - \frac{F_B\,B}{F_A\,A}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16a)$$

and

$$e_B = \frac{2}{4 - \frac{F_A\,A}{F_B\,B}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16b)$$

These factors vary from $\frac{2}{3}$ for a symmetrical square panel to 1 for a panel in which the rectangularity is 2, indicating a uniformly distributed load that approaches the condition of one-way construction.

All required values for F_A, r_A, e_A, etc, are tabulated for ready reference in the A. C. I. Code, from which equivalent uniform loads $e_A\,r_A\,w$ and $e_B\,r_B\,w$, to be carried in each direction, can be obtained directly. Bending moments are then computed exactly as for one-way construction by loading successive spans in each direction with their equivalent uniform loads. This procedure is theoretically feasible because of the phenomenon of redistribution of stress that results in the curve of bending moments across the width of the panel being so flattened out that designs may be based on the average moment that corresponds to about 72% of the maximum theoretical moment without this provision.

The A. C. I. Code also covers the design of the supporting beams on the statical principle that beams and parallel slab together carry the total load in each direction. Thus, corresponding equivalent uniform unit loads for beam design are $(1 - e_A\, r_A)w$ and $(1 - e_B\, r_B)w$.

An interesting comparison results from an extension of Table 2 to include the authors' values reduced for redistribution of stress (see Table 4). It is to be noted that the average ordinate of a sine curve is about 64% of the maximum. Therefore, a 36% reduction of moments derived by the sine-curve method may be more nearly correct. Both values are shown. The reasonably close agreement between either of these values and the A. C. I. Code is apparent, and affords definite evidence of its accuracy and reliability in the practical design of unequal panels.

TABLE 4.—Edge Moments Redistributed for Stress

Description	M_{12}	M_{23}	M_{45}	M_{56}	M_{14}	M_{25}	M_{36}

A. C. I.	13.18	9.20	3.54	2.94	8.18	5.84	2.80

Sine-curve distribution as developed by the authors is a noteworthy contribution to the analysis of continuous slabs supported on four sides. It provides a method by which the moments in a series of unequal panels of varying degrees of rectangularity may be solved with relative simplicity. The discussion of the effect of Poisson's ratio on positive moments is of technical interest, but has limited scope in reinforced-concrete design where the slabs are subject to tension cracking under working loads. If the formulas are modified to include the effect of redistribution of stress, a useful tool will result for checking practical design constants and methods.

Ralph E. Byrne, Jr.,[13] **Jun. Am. Soc. C. E.**—A comparatively simple method of analyzing a very complex problem is presented in this paper. The method is admittedly approximate, and yet, in the particular case presented in the paper, it produces results that are quite satisfactory for design purposes.

Its most striking feature is that the complicated problem of a continuous slab is reduced to the much simpler problem of a continuous beam. Consequently, the various methods of solving continuous beam problems are made available for the solution of continuous slab problems. In the theory of continuous beams, methods of distributing moments,[14] and of distributing angle changes,[15] have been developed primarily to avoid the necessity of solving a large number of simultaneous algebraic equations. The latter method (balancing angle changes) is well adapted to the solution of the slab problem as presented by the authors.

[13] Mathematical Physicist, Barber-Coleman Co., Rockford, Ill.

[14] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[15] "Analysis of Continuous Frames by Balancing Angle Changes," by L. E. Grinter, *loc. cit.*, Vol. 102 (1937), p. 1020.

Each slab is considered as simply supported and the angles ϕ_s are determined from Fig. 5, or otherwise. At each support in turn, continuity is restored by applying a moment (the same moment to each slab meeting at the support); and the change in angle, θ, for each slab, caused by this moment, is directly proportional to the factor α (Fig. 4) for the corresponding slab. It is assumed that during this process of restoring continuity on one side, the other sides remain simply supported. Consequently, the three remaining sides will be rotated also, the amount of this rotation being equal to θ (the rotation of the side on which continuity has been restored temporarily) multiplied by a carry-over factor. These carry-over factors are seen to be $C_\beta = \frac{\beta}{\alpha}$ and $C_\gamma = \frac{\gamma}{\alpha}$ for the opposite and adjacent sides, respectively, β and γ being given in Fig. 4.

The process to be followed is thus a well-known one. Continuity is first restored at each side of the various slabs. The angles which, as a consequence, must be carried to the other sides of each slab are determined, and again continuity is restored by the balancing process. This sequence of operations is repeated until the results have converged to within the required limits of accuracy. The only difference between the foregoing process and the well-known one for continuous beams is that it is necessary to consider three carry-over factors, instead of one, for each member at each support.

By this process, the angles θ_{ij} (as defined by the authors) are determined for each support of each slab; and now, to determine the moments, four equations of the type of Eq. 8 must be written, one equation for the angle at each side of a slab panel. These equations are then to be inverted to give the moments as functions of the angles. Let the subscripts a and b refer to quantities relating to the sides of the slab panel of lengths a and b respectively; and let subscripts 1 and 2 further distinguish quantities relating to the sides of the same length. Write

$$\psi = \theta - \phi_s \tag{17}$$

With this notation, the aforementioned equations of the type of Eq. 8 become

$$\left.\begin{aligned}
a\,\alpha_a\,M_{a1} + a\,\beta_a\,M_{a2} + b\,\gamma_b\,(M_{b1} + M_{b2}) &= D\,\psi_{a1}\\
a\,\beta_a\,M_{a1} + a\,\alpha_a\,M_{a2} + b\,\gamma_b\,(M_{b1} + M_{b2}) &= D\,\psi_{a2}\\
a\,\gamma_a\,(M_{a1} + M_{a2}) + b\,\alpha_b\,M_{b1} + b\,\beta_b\,M_{b2} &= D\,\psi_{b1}\\
a\,\gamma_a\,(M_{a1} + M_{a2}) + b\,\beta_b\,M_{b1} + b\,\alpha_b\,M_{b2} &= D\,\psi_{b2}
\end{aligned}\right\} \tag{18}$$

Eqs. 18 are easily inverted to give the moments, as follows:

$$\left.\begin{aligned}
M_{a1} &= \frac{D\,(\alpha_b - \beta_b)}{a\,\Delta}\,[A_a\,\psi_{a1} + B_a\,\psi_{a2} + C_a\,(\psi_{b1} + \psi_{b2})]\\
M_{a2} &= \frac{D\,(\alpha_b - \beta_b)}{a\,\Delta}\,[B_a\,\psi_{a1} + A_a\,\psi_{a2} + C_a\,(\psi_{b1} + \psi_{b2})]\\
M_{b1} &= \frac{D\,(\alpha_a - \beta_a)}{b\,\Delta}\,[C_b\,(\psi_{a1} + \psi_{a2}) + A_b\,\psi_{b1} + B_b\,\psi_{b2}]\\
M_{b2} &= \frac{D\,(\alpha_a - \beta_a)}{b\,\Delta}\,[C_b\,(\psi_{a1} + \psi_{a2}) + B_b\,\psi_{b1} + A_b\,\psi_{b2}]
\end{aligned}\right\} \tag{19}$$

FIG. 9.—DETERMINATION OF THE ANGLES θ BY DISTRIBUTING ANGLE CHANGES

The several quantities used in writing Eqs. 19 are defined as follows:

$$\left.\begin{aligned}
\Delta &= (\alpha_a - \beta_a)(\alpha_b - \beta_b)[(\alpha_a + \beta_a)(\alpha_b + \beta_b) - 4\,\gamma_a\,\gamma_b] \\
A_a &= \alpha_a\,(\alpha_b + \beta_b) - 2\,\gamma_a\,\gamma_b \\
B_a &= -\,[\beta_a\,(\alpha_b + \beta_b) - 2\,\gamma_a\,\gamma_b] \\
C_a &= -\,\gamma_b\,(\alpha_a - \beta_a) \\
A_b &= \alpha_b\,(\alpha_a + \beta_a) - 2\,\gamma_a\,\gamma_b \\
B_b &= -\,[\beta_b\,(\alpha_a + \beta_a) - 2\,\gamma_a\,\gamma_b] \\
C_b &= -\,\gamma_a\,(\alpha_b - \beta_b)
\end{aligned}\right\}\dots\dots(20)$$

It is to be noted that Eqs. 19 are exactly analogous to the slope-deflection equations of beam theory. Having determined the moments from these equations, the accuracy of the entire process may be judged by the agreement of moments at the supports as computed from the angles of the two adjoining slab panels, and by the computed magnitude of moments over supports that have been assumed to be simply supported.

By this method the writer has recomputed the example given by the authors, and the results obtained are in substantial agreement with the authors' results as given in Table 2. The computation of the angles θ by the balancing process is shown in Fig. 9. The computations are so arranged that, for each support, the left-hand column shows the angles for simple support, ϕ_s, each carry-over angle, and each balancing angle; the right-hand column shows the cumulative total after each balancing. The convergence in this example is not rapid; and such cumulative totals not only give a means of judging the degree of convergence, but also, when the balancing process is terminated, they give a means of estimating a better value of the angle θ than the final number in the cumulative total column. Thus, the final angles θ to be used in computing moments were estimated from consideration of the sequence of numbers appearing in the cumulative-totals column.

The computation of moments from the angles thus obtained is a matter of straightforward substitution in Eqs. 19; a convenient tabular form will immediately suggest itself to the computer. The results obtained in this manner are shown in Table 5. The last five moments of this table are computed moments over supports that were assumed to be hinged, and are seen to be small compared to the other moments of the corresponding panels. The remaining moments agree substantially with the authors' results (see Table 2).

Theoretically, it would be possible to apply the method of distribution of moments in a similar manner. However, there are several practical difficulties. The starting point of this process is the determination of "fixed-end moments"—that is, the moment at the center of each edge of each slab when the conditions of fixity are satisfied along these edges. Likewise, "stiffness" and "carry-over" factors must be computed, one edge being rotated through a unit angle while the other edges are held fixed, and the corresponding moments at the centers of the four edges determined. The computation of these quantities for the fixed slab is essentially more difficult than the computation of the corresponding quantities for the simply supported slab. Furthermore, the assumption, in the former case, of a sine distribution of moment along the edges is not as natural an assumption to make as in the latter case. Nevertheless, should these quantities be available for the fixed slabs, the method of distributing moments would be immediately applicable to the problem.

In conclusion, it should be stated that no superiority is claimed for the methods herein suggested over that used by the authors; they are essentially the same. Rather, it has been the purpose of this discussion to point out the analogy between the theory presented in this paper and beam theory, and to suggest other possible methods of attack on the problems that present themselves as a natural consequence of this analogy.

PIERCE P. FURBER,[16] M. AM. SOC. C. E.—Eqs. 13 have been written incorrectly, thus leading to an erroneous conclusion, which is not a little surprising.

Lateral deformation in a body has long been recognized as of opposite sign to the direct strain. Works on elasticity treat the subject in general. Experimental determinations of the ratio of lateral deformation have been made for many materials, by many men. Poisson was among the pioneers; hence, his name has been connected with it.

The theory of elasticity shows that like strains or deformations at right angles are accompanied by lateral deformations of the opposite sign, in each direction. Consequently, the primary strains are reduced by some amount. In a plate or slab under load, therefore, the extensions and compressions are both reduced, to some extent, by the lateral deformations. The true stresses are less, and hence the true moments of resistance in each direction are less than the apparent moments. Eqs. 13 should be written: $M_x = M'_x - \mu M'_y$, etc.

Engineers of varying opinions have engaged in spirited controversy concerning not only the value of Poisson's ratio for reinforced-concrete slabs, but whether any value at all existed for it. Some seemed to believe that the composite plate of concrete and steel constituted an exception to the general theory of elasticity in that respect. However, scientific explanations for that view have been entirely lacking.

The paper contains the first statement the writer has noticed that the effect of lateral deformations is actually to increase the moments (and consequently the stresses) in a slab or plate supported on four sides. As the paper seems not to limit the equations to reinforced concrete, these formulas must be intended to apply as well to other materials.

---

[16] Structural Engr., Ford, Bacon & Davis, Inc., Pottstown, Pa.

L. C. MAUGH,[17] ASSOC. M. AM. SOC. C. E.—In Mr. Van Buren's discussion he mentioned that the fundamental relationships used in deriving the various algebraic expressions, and the numerical values of the slopes and moments, given in the various diagrams, were not stated. These factors will now be considered and the basic principles of the solution given.

The basis of all values is the solution of Lagrange's equation for the flexure of plates, namely

$$\frac{\partial^4 w}{\partial x^4} + 2\,\frac{\partial^4 w}{\partial x^2\,\partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{P}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Any displacement surface, whose values are designated by w, which satisfies this equation will also satisfy the equilibrium and continuity conditions for every element of the slab. It is also assumed that the principle of superposition applies and therefore the displacements can be calculated separately for the applied loads and for the edge moments and then combined to give the total value. The solution of Eq. 21 for the types of loading considered in the paper was made by Levy's method which represents the deflection surface by a Fourier series in the form

$$w = \sum_{n=1}^{\infty} Y(m) \sin \frac{m\,\pi\,x}{a} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

in which $Y(m)$ is a function of y only. As the application of Levy's method to the solution of slab problems can be found in various books and technical periodicals,[7] it will not be repeated. As stated in the paper this solution enables the slopes and moments to be represented by a sine series which, in most cases, is rapidly convergent. If the edge moments are also represented by a similar sine series as Eq. 4, then an exact solution for the value of these moments can be made as explained in the "Introduction." However, in the approximate solution, the edge moments were represented by the first term of the series so as to simplify the equations. Nevertheless, all displacements, slopes, and moments due to the edge moments were determined by the solution of Eq. 21 and therefore satisfy the shearing, flexural, and torsional resistances of the slab.

After the deflection surface was obtained from Eq. 21, the slopes and moments were obtained from the following equations:

$$\theta_x = \frac{\partial w}{\partial x} \quad \text{and} \quad \theta_y = \frac{\partial w}{\partial y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

and

$$\left.\begin{aligned} M_x &= -\,D\left(\frac{\partial^2 w}{\partial x^2} + \mu\,\frac{\partial^2 w}{\partial y^2}\right) \\ M_y &= -\,D\left(\frac{\partial^2 w}{\partial y^2} + \mu\,\frac{\partial^2 w}{\partial x^2}\right) \\ M_{xy} &= -\,D\,(1-\mu)\,\frac{\partial^2 w}{\partial x\,\partial y} \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots (24)$$

---

[17] Asst. Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

When Poisson's ratio μ is assumed equal to zero, the value of the moments becomes

$$\left.\begin{aligned} M'_x &= -D\frac{\partial^2 w}{\partial x^2} \\ M'_y &= -D\frac{\partial^2 w}{\partial y^2} \end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(25)$$

which are in the same form as for a beam. By comparing Eqs. 24 and 25, it can be seen that the relations given by Eq. 13 are correct.

In making the calculations, the bending moments are computed at the center of the slab and the middle of the supports although it is known that the absolute maximum values do not necessarily occur at these points. No redistribution of the edge moments was made for the reason that the writer is not at all certain just how this yielding at one point affects the entire slab. When the end connection of a beam yields one knows that the moment at the center increases. In a slab, however, it is doubtful if the moment at the center increases correspondingly until yielding has progressed some distance along the support. As the rotation at the middle of the support increases, there will be some increase in the torsional moment in that vicinity and therefore some increase in the edge moments contiguous to that zone. However, the determination of the amount of this redistribution and its effect upon the ultimate strength of the slab appear to be a matter of judgment and consequently should be made after the theoretical values are obtained. Nevertheless, the writers are indebted to Mr. Van Buren for his discussion of this subject. His recalculation of the edge moments on the basis of some redistribution as tabulated in Table 4 give an interesting comparison with the corresponding values that were computed by the A. C. I. Code. The values computed by the exact formulas would have to be reduced by percentages varying from about 10% to 42% to equal the values obtained by the A. C. I. Code. If a reduction is to be made it should be a constant ratio. The results indicate that the values given by the A. C. I. Code, considering an allowance of about 32% for redistribution, are fairly accurate when the adjacent panels are approximately of the same dimensions.

The use of the slopes as unknowns rather than the moments, as illustrated by the solution submitted by Mr. Byrne, may be advantageous for certain types of problems. For example, if the torsional resistance of the beam is to be included, this factor could be introduced in terms of the rotation angle. For the type of problems considered in the paper, however, the algebraic arrangement that is used was chosen after an investigation of both the moment distribution and slope methods. If Eqs. 11 are written in the following form (p equal to unity)—

$$\left.\begin{aligned} M_{12} &= -25.0 - 0.144\,M_{23} - 0.10\,(M_{14} + M_{25}) \\ M_{23} &= -16.4 - 0.131\,M_{12} - 0.091\,M_{25} - 0.033\,M_{36} \\ M_{45} &= -11.45 - 0.034\,M_{56} - 0.382\,(M_{14} + M_{25}) \\ M_{56} &= -9.15 - 0.031\,M_{45} - 0.351\,M_{25} - 0.265\,M_{36} \\ M_{14} &= -16.0 - 0.167\,M_{12} - 0.066\,M_{45} \\ M_{25} &= -16.0 - 0.167\,(M_{12} + M_{23}) - 0.066\,(M_{45} + M_{56}) \\ M_{36} &= -9.65 - 0.358\,M_{23} - 0.264\,M_{56} \end{aligned}\right\}\ldots(26)$$

—the solution can be made with a slide rule by means of the method of iteration. The rate of convergence is shown by the values for successive cycles as recorded in Table 6(*a*).

TABLE 6.—SOLUTION BY THE METHOD OF ITERATION

Cycle	M_{12}	M_{23}	M_{45}	M_{56}	M_{14}	M_{25}	M_{36}
(*a*) GENERAL CASE							
0	−25.0	−16.4	−11.45	−9.15	−16.0	−16.0	−9.65
1	−19.44	−12.09	+ 3.89	−1.10	−13.02	−10.93	−2.40
2	−20.86	−12.58	− 2.26	−4.61	−12.61	− 9.97	−3.93
3	−20.93	−12.62	− 2.66	−4.53	−12.34	− 9.93	−3.94
4	......	......	− 2.80	−4.52	......	......	......
(*b*) SPECIAL CASE							
0	−12.50	0	0	0	−11.10	0	0
1	−11.39	+ 1.49	+ 4.24	−0.13	− 9.50	+ 1.38	−0.50
2	−11.90	+ 1.44	+ 3.10	−0.45	− 9.30	+ 1.38	−0.40

The values that are given in the second cycle of Table 6(*a*) are sufficiently accurate for all practical purposes, except M_{45} which should be taken to at least three cycles. In making the calculations in this manner, it is often convenient to combine certain equations so as to reduce the number. When different loading conditions are used in the various spans, only the constant term in the equations need be changed. Thus, if only panels 1 and 1′, Fig. 6, are loaded, the values in Table 6(*a*) would be changed to the values given in Table 6(*b*).

For these edge moments, the moments at the center of panels 1 and 4 are

$$\left.\begin{aligned} M_{x1} &= (0.0618)(15)^2\,p - (0.144)(11.9)\,p - (0.123)(9.3)\,p = +\,11.0\,p \\ M_{y1} &= (0.032)(15)^2\,p - (0.1365)(11.9\,p) - (0.0015)(9.3\,p) = +\,5.6\,p \\ M_{x4} &= (2)(0.13)(-\,9.30\,p) - (0.017)(3.10\,p) = -\,2.47\,p \\ M_{y4} &= (2)(0.18)(-\,9.30\,p) + (0.108)(3.10\,p) = -\,3.0\,p \end{aligned}\right\}\;..(27)$$

Combinations of different panel loading and different types of loading can be used in the equations without much difficulty. The most common source of error is likely to be the interchanging of sides *a* and *b* when calculating the moments at the center of the panel.

Mr. Furber has apparently confused action and reaction when considering the sign of Eq. 13. This equation is no different from the usual expression for the two-dimensional state of stress in terms of the corresponding strains. Thus, if f_x, f_y, e_x, and e_y represent the unit stresses and strains acting upon any element in the x and y directions, respectively, the relationship between them is given by the following equations:

$$\left.\begin{aligned} e_x &= \frac{f_x}{E} - \mu\,\frac{f_y}{E} \\ e_y &= -\,\mu\,\frac{f_x}{E} + \frac{f_y}{E} \end{aligned}\right\}\;.......................(28)$$

Solving these equations for f_x and f_y gives

$$\left.\begin{aligned} f_x &= \left(\frac{E}{1-\mu^2}\right)(e_x + \mu\, e_y) \\ f_y &= \left(\frac{E}{1-\mu^2}\right)(e_y + \mu\, e_x) \end{aligned}\right\} \quad \cdots\cdots (29)$$

Therefore, if $\left(\frac{E}{1-\mu^2}\right) e_x$ is represented by f'_x, and $\left(\frac{E}{1-\mu^2}\right) e_y$ is represented by f'_y, the corresponding stresses for a one-dimensional stress system, the equations become

$$\left.\begin{aligned} f_x &= f'_x + \mu\, f'_y \\ f_y &= f'_y + \mu\, f'_x \end{aligned}\right\} \quad \cdots\cdots (30)$$

which can be translated into moments in the usual manner.

In preparing this final discussion the writer deeply regrets that the co-author, C. W. Pan, is unable to participate because of his duties with the Chinese National Government. Present conditions, however, render communication practically impossible.

Paper No. 2155

TRAFFIC ENGINEERING AS APPLIED TO RURAL HIGHWAYS

By Milton Harris,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Charles E. Conover, Stephen E. Butterfield, Nathan Cherniack, Park H. Martin, and Charles M. Noble.

Synopsis

Highways are built for one purpose only—to carry traffic. In the operation of American rural highway systems two problems have to be faced:

1. To modernize existing roads so that they may meet the demands of efficient transportation.

2. To incorporate in new design those elements that study of existing traffic has taught are efficient factors.

This paper presents various techniques for accomplishing these ends in part.

Introduction

The practice and literature of traffic engineering heretofore have been applied principally to city streets and the environs of urban areas. As a result, investigations have been narrowed to those items that directly affect this type of traffic native to these localities. Corrective measures in general have been confined to erecting signs, parking, placing, and operating traffic signals, channelizing and alleviating conditions that are conducive to high accident frequency at intersections.

The problem of moving rural traffic safely and speedily now demands attention and, in fact, has come to be regarded as of major importance. Its insistence lies in the fact that although the actual number of accidents inside American urban areas is greater, nevertheless by comparison those that occur outside are the more severe and cause a greater number of fatalities.

To fully appreciate the problem that lies before the highway engineer, it is necessary to give some thought to the fundamentals of traffic that produce these troubles. Of two schools of thought, one considers traffic as a homogeneous stream and the other, as made up of individual units to be dealt with singly and individually. Education and enforcement take the latter view,

---

Note.—Published in May, 1941, *Proceedings*.

[1] Associate Highway Engr., California Div. of Highways, Sacramento, Calif.

but engineering has to consider the former. Both activities may function in unison.

Taken as an individual, the motorist indulges in a variety of antics that express his own personality and training. Even he himself cannot realize why he does certain things in a particular manner. Taken as mass behavior, however, such actions are reasonably capable of being measured and valued. Experience shows that this mass action follows certain definite patterns, as affected by each motorist's individual life and surroundings. In certain localities vast numbers drive to work at 7:45 a.m. Each has to be at work at eight, and each leaves his home at a different minute, yet the mass moves down the street at a particular time of day.

This stream of cars proceeds at a certain speed, as regulated by the individual's sense of caution and by his reaction to the surrounding physical features. Most drivers follow a definite pattern that is as fixed as the time at which this mass movement takes place. Because traffic follows such a pattern to a great extent the traffic engineer can define the pattern's extent and may cause it to change by introducing human and physical factors. The human factors are the police with their regulatory functions and the educators with their teaching propaganda. The physical factors are the surrounding terrain, signs, signals, stripes, islands, and kindred design of the highway structure. Whatever the origin, the least change affects the traffic stream.

Traffic psychology is complex and as yet unsolved; although it may be expected that certain obvious changes will affect the stream flow in certain ways. No one knows what effect certain types of buildings, certain visibility, or certain other contiguous traffic streams will have on a particular flow of traffic. This type of research should be undertaken in the near future. It seems strange that so much accuracy in detail of design of highways should obtain, whereas so little is known about the element that will use the road.

By analyzing traffic action, traffic behavior can be determined and evaluated. Roads should be built accordingly; hence, it seems reasonable to expect a road design that will accommodate that behavior which is normal to those who drive with prudence.

If all these deductions are valid, they serve as a basis for further development of the thought that engineering principles may be applied to traffic flow and traffic trouble as well as to the analysis of liquid flow or liquid disturbances. Underlying all, there seems to be a pattern. It is the engineer's problem to identify this pattern and, if an adverse one, to effect a change by altering either the physical structure or the human regulation and education of the traffic stream. Doubtless, driving habits can be changed by education and by enforcement, but more probably can be accomplished by natural regulation resulting from properly designed highways which accommodate themselves to reasonable existing traffic patterns, aided at proper points by efficient regulation rather than by severe enforcement.

In applying traffic engineering to rural highways the most outstanding feature that needs correcting is the present structure, which must be made safe for existing traffic. The crying need is to reduce the large mortality on streets and highways, yet provide the maximum mobility possible for users.

Next in order, it is essential to provide designers with traffic data so that future roads will be the most efficient obtainable with the money available. These two projects should occupy the immediate attention of traffic engineers until the hazards have been brought under control. After that, other needs of traffic should be subjected to engineering examination in the order of their importance. Among the problems requiring consideration are congestion, pedestrian control, freeways, allocation of tax moneys, roadside development, integration of transportation facilities, and many other worth-while projects.

This paper will be limited to two phases of the traffic engineering problem: (1) Modernization of present facilities by investigating hazardous locations; and (2) utilization of traffic data for design.

POINTS OF HAZARD

In any engineering investigation the collection of the facts appertaining to the problem is the first consideration. Then comes their arrangement in such manner that they may be studied and pertinent conclusions drawn. In the study of rural accidents, first it must be known (*a*) where, (*b*) when, and (*c*) why the accidents happened; then from these facts logical conclusions can be drawn and reasonable recommendation made for the remedy.

So long as accidents are distributed along a highway and their frequency is proportioned to the density of traffic—or as it is termed, the accidents are proportional to traffic exposure—there is little that can be done in attacking the problem from an engineering standpoint; but let one particular location become the focal point for more than a very few accidents and the engineer has a sample on which to start work. He can analyze the facts for the pattern involved. Not that it is necessary to have accidents at a particular point before an investigation can be started; but the fact remains that ordinarily records are already available, and more are being accumulated, to establish these points of accident frequency as the localities that demand immediate attention. As will be shown later, direct investigation of driver habit can be made in the field without recourse to the accident record, other than its location.

To locate these points of recurrence, so that investigation may be made, "pin maps," "spot cards," or "concentric circles" (Fig. 1) may be used to show where a "pile up" is taking place. Having collected, coded, entered, and filed the accident reports, the most hazardous location on a particular stretch of highway is at once apparent. The next step is to determine "why." This process is usually a comparatively simple procedure in city work, inasmuch as an analysis of the accidents that have occurred generally indicates the solution at once. In rural investigations the causes are more obscure; they are numerous and often are not mentioned in the reports because they were not apparent to the patrol officer at the time. For this reason a different technique is suggested to overcome any lack of information.

This technique is based on the premise that the accident reports reflect certain bad driving habits on the part of some motorists using that particular highway. Due to the changeability of such habits as affected by external influences, it necessarily follows that no two points on a highway will have the same effect. Hence, the investigation must be confined to a relatively small portion or area if the reason is to be determined for a series of accidents at that point.

To indicate those bad driving habits, the accident reports themselves are analyzed for all their elements. Usually one or more outstanding contributory causes motivate the underlying pattern. These are used as indicators with which the traffic engineer arms himself before going out into the field to ascertain the proportion of the traffic that indulges in questionable practices.

FIG. 1.—ACCIDENT INVENTORY

He must use his ingenuity to devise tests to determine these causes. His tests must be extensive and accurate enough to give him results that are trustworthy, because from his results the engineer must formulate a remedy that will exclude habits conducive to accidents, without at the same time introducing other and more severe hazards. It is true that any change may introduce an element giving rise to another habit which in turn may produce accidents, but these accidents should be of a different type. Sometimes it may even be advisable to deliberately introduce into the highway structure a physical change that will convert one type of accident into another less dangerous. For example, a division strip built into a four-lane highway should eliminate head-on accidents, or medial friction, which in rural sections ordinarily results in many fatalities because of the high speeds involved; but a preponderance of rear-end accidents may then occur. However, these are not usually so severe as the head-on type; and by further application of investigative technique, remedies for the rear-end type will be found.

For ease in analyzing accident report data it is customary to list on a summary form the various factors that have been reported for each accident, arranged across the page, one accident to the line, as shown in Fig. 2. (The notation for the driver in the third item as "HBD" is code for "Had been drinking".) By adding up all factors and expressing them as percentages, their relation to each other is noted as one element of the problem, and their relation to state-wide statistics gives immediate indication as to what factors of the problem are worthy of investigation as indicated in Table 1, which relates to the same location as Fig. 2. In fact, comparison of factors, either within the problem or externally with the state-wide data, indicates the accident pattern in many cases. In the example cited, speed is the outstanding contributory cause; hence this can be taken as the indicator for further study in the field.

FIG. 2.—TABULATION

fact, it is actually making a traffic survey for use in designing a change in traffic behavior. Of many methods, one is shown in Fig. 3, by photography.

In many cases, a field check of those driver habits, suspected of contributing to the hazard of an accident-prone location, will reveal that the "indicators" are erroneous. In this event, a careful study must be made of the traffic flow and every phase analyzed by partial counts until the crux of the situation is found. Many hours of careful scrutiny may be required. It may also be necessary to return many times to observe traffic at various stages of density as well as under varying conditions of light and weather. It is entirely possible to ascertain and isolate those malign traffic habits from observation alone without prior recourse to an accident summary analysis, though, of course, the analysis sheet is a great help as a starter. Sometimes information secured from local residents or from a study of marks caused by accidents is useful in picking out leads that might indicate the patterns sought. Local police or highway officers often are familiar with the data sought and can be of great help if approached in a diplomatic manner.

The next step is to assemble and analyze the field data, and from them draw whatever conclusion is justified. Most of them may be shown in comprehensive form by means of charts or curves, which are valuable in studying the significance of the facts recorded and also useful for inclusion in a report on the problem (Fig. 4). It is advisable to completely analyze all data taken, because in them may lie the answer to a question that is formed in the mind of a person reading the report, which question eventually would have to be answered.

Applying a physical remedy to a traffic danger demands wide knowledge of highway construction procedure and costs. Obviously, it also requires an expert knowledge of the effect that the new construction will have on the traffic

								1-4					A northbound at speed excessive for conditions hit B southbound in southbound lane.	

of Accident Data

stream. Even solutions that seem obvious may produce changes in traffic habits that react unfavorably. An example is the use of three-lane pavements over vertical curves with insufficient sight distance.

The physical remedies devised so far might be classified as changes in the geometric design to accommodate prevailing traffic habits, as follows:

(1) Separation of parallel lanes of traffic;
(2) Separation of intersecting lanes of traffic;
(3) Separation of traffic into lanes of varying speed;
(4) Isolation of various turning movements by means of channelizing islands;
(5) Control of movements by means of signs, signals, lighting, and stripes;
(6) Parking provisions.

Other remedies made by the application of human forces may be effected by means of supervision, enforcement, and education. Application of these remedies is within the realm of traffic engineering, but presupposes a knowledge of traffic police methods, modern educational methods, and public relationship. Their use must be predicated on a complete analysis that indicates a stronger probability of success by such measures than by others within the means of the traffic engineer. He is not limited to physical changes. Some have gone so far as to suggest the combining of the administration of all remedial functions into a highway "operating" department.

In applying remedies to traffic conditions, the item of economics is of direct concern to the traffic engineer. Remedial measures may well be promulgated by any layman but their justification often will not "hold water" from the standpoint of money required for their accomplishment. Much research must be conducted before the traffic engineer can evaluate such factors as fatalities

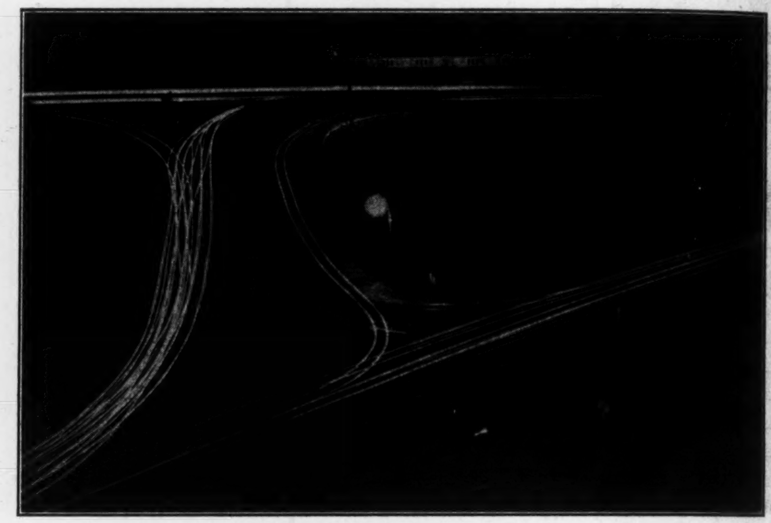

FIG. 3.—TRAFFIC MOVEMENTS TRACED BY PHOTOGRAPHING MOVING HEADLIGHTS. NOTE ONE WRONG ROUTE NEAR CENTRAL LIGHT

and personal injuries, loss of time caused by congestion, cost of car operation when used for pleasure, and others. The answer may lie equally in either engineering or policing, and the final solution may be determined by the relative economies possible. The evaluation of death from the standpoint of insurance risk does not seem to cover the situation except when used on a comparative basis, but the mere totals of deaths or permanent disabilities act as a most potent weapon when waved before the noses of those who must approve the appropriation of funds to correct a hazardous condition.

FIG. 4.—GRAPHIC TRAFFIC DATA FOR ONE INTERSECTION

To show the application to practical problems, a few cases will be analyzed in detail.

CASE NO. 1.—PROBLEM OF DANGEROUS CURVE

It will be presumed that a spot card such as Fig. 1(*b*) has been examined, and the location at mile 5 appears to present a hazard that demands attention in relation to other points of accident occurrence on this highway. A perusal of the individual accident reports is made and an accident summary sheet prepared, as shown in Fig. 2. The contributing factors have been summed up and their percentages calculated for purposes of comparison (Table 1) including a partial comparison with state-wide totals.

Those items that exhibit a tendency to depart from the normal expectancy are immediately used as possible indicators—in this case "single cars", and "speed." From knowledge gained through experience and a study of statistics, it is known that in general a preponderance of single-car accidents points either to a road fault or to drunken driving. Speed and road conditions can be checked in the field.

A collision diagram or pictorial representation of the course of vehicles prior to collision (Fig. 5) is a great help in analysis, especially when used with the corresponding summary sheet (Fig. 2). Notations are the same in both. It will be noted that each accident has happened on the outside of the curve, which important fact will find its place in the complete analysis as shown subsequently.

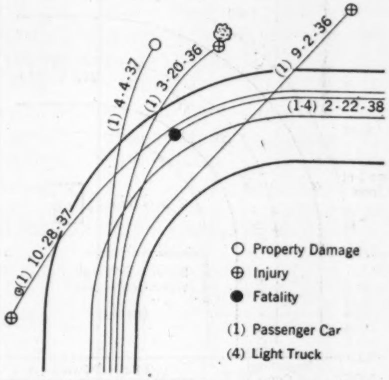

FIG. 5.—COLLISION DIAGRAM, FOR DATA OF FIG. 2 (ILLUSTRATIVE CASE 1)

In this problem the field work consisted of making a site plan of the area (sometimes known as a "condition diagram"); then a survey of the highway itself by means of a five-line profile; and finally a series of speed checks to determine the prevailing speeds. The field results are shown in Fig. 6. In the results of one of the speed checks, plotted as a mass diagram (Fig. 6(*c*)), the curve breaks sharply at approximately 85%, indicating that the increments of speeds up to that point have been used by fairly uniform numbers of drivers; but that above this point, there is a rapid falling off. The "break" of the curve has been designated as the "critical speed" and indicates the top speed that the majority of motorists consider safe for that particular spot under the conditions prevailing at the time of test. The entire curve represents the pattern of drivers' habits, whereas the critical speed represents their habit of top safe speed. Obviously, those who exceed the critical speed are the minority, and they are always present no matter how high the critical speed of the sane drivers. A highway capable of accommodating 100% of the driving range could not be financed practicably even if it were otherwise attainable.

Having determined the prevailing speed, the next logical step is to ascertain if the conditions obtaining are safe to accommodate these speeds. It is noted that the speed of approach to the curve is approximately 50 miles per hr. From Fig. 6(*b*) the superelevation is shown to be only 0.1 ft. One formula for centrifugal motion gives the relationship

$$S + f = \frac{0.067\, V^2}{r} \qquad (1)$$

in which: S = rate of superelevation, as a decimal; f = coefficient of friction (0.16); V = velocity in miles per hour (50 miles per hr); and r = radius of curve in feet (500 ft).

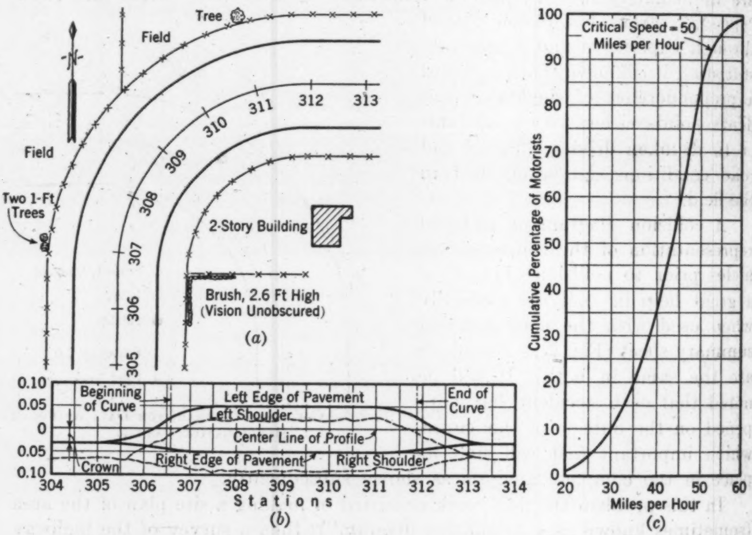

FIG. 6.—SUPPLEMENTARY DATA, INCLUDING (*a*) SITE PLAN, (*b*) FIVE-LINE PROFILE, (*c*) SPEED CHECKS

Applying Eq. 1, it is found that S should be 0.175 as compared with 0.005 obtaining on the ground. This verifies the suspicion that speed too great for conditions prevails at this curve and accounts for the large number of accidents that took a course to the outside of the curve. Even the two-car accident occurred in the outside lane and was evidently caused by the northbound car traveling at too great a speed to keep within its own lane. The single-car accidents occurred on the outside part for the same reason, even though one accident showed drinking as a contributing cause.

Taking the actual $S = 0.005$ and solving Eq. 1 gives a safe $V = 35$ miles per hr satisfied by only 19% of the drivers. One may well wonder what happens to the 81% traveling at a speed in excess of that which is theoretically safe. Examination of the traffic habits on the ground showed that a considerable number of drivers applied their brakes upon reaching this curve and in some cases the rear wheels chattered and skidded sideways as the driver attempted to bring the vehicle under control. A test car was able to negotiate the curve at the top speed of 37 miles per hr without undue sway, which checks very closely with the speed by Eq. 1.

The apparent remedy in this case is to change the superelevation. Obviously, a superelevation of 0.175 is too great to accommodate the slow traffic. In addition, weather conditions, types of vehicles, and their loads may be so affected by such a superelevation as to become a hazard in turn. In practice a superelevation of 0.1 ft per ft of width ($S = 0.1$) is about the maximum that will safely provide for all types of traffic. Using this value and solving for R, the problem resolves itself into relocating the curve to a radius of 644 ft with a maximum superelevation of 0.1 ft per ft of width.

As the design speed for the new curve, the critical speed that obtains at the approach was selected; but there is likely to be an increase in this after the new construction is put into operation. If the curve were to be much flattened and the approach environment changed so that traffic probably would increase its speed at this point, then it would be in order to select a higher design speed than is here indicated. Speed checks taken at comparable locations that have been improved to the proposed standards will often furnish reliable data upon which to base judgment as to proper design speed.

[a] In terms of number of times reported; possibly several different causes for one accident.

CASE NO. 2.—ZONE INVOLVING ACCIDENTS

For a section several miles long, the spot cards indicated a series of accidents greater than adjacent areas on the same route, yet with no particular concentration. The summary analysis sheet (Table 2) indicated that "Had Been Drinking" was the cause that appeared most frequently. Drinking habits are scarcely capable of being analyzed by means of a traffic survey, hence recourse was made to another angle of approach. In Fig. 7 the accidents are plotted according to the hour of occurrence. For comparison, the traffic flow is also shown.

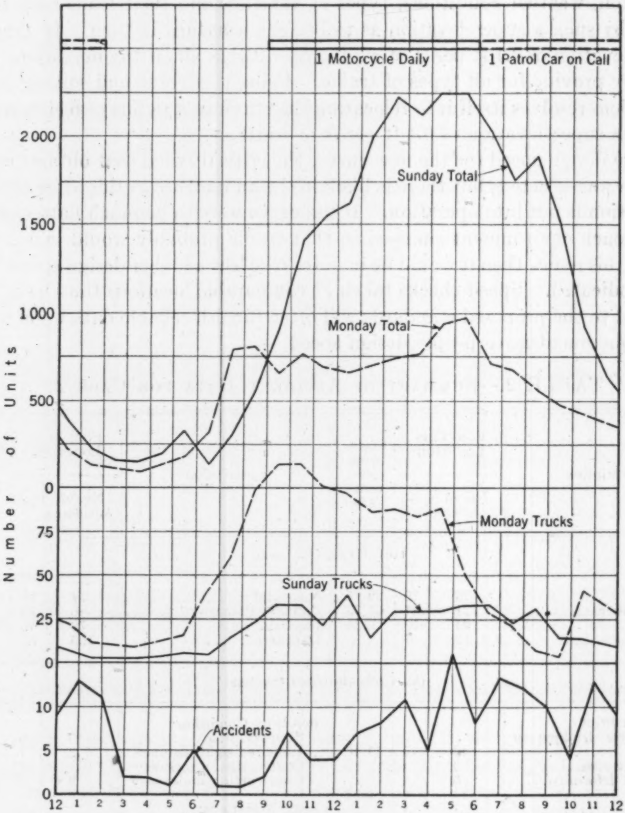

FIG. 7.—GRAPHIC DISTRIBUTION OF TRAFFIC AND ACCIDENTS, CASE 2

From the law of averages, it is reasonable to predict that more accidents will occur during the peak hours of traffic than at other hours, because of the exposure of a greater number of vehicles. The curve shows this to be the case, as between 4 p.m. and 6 p.m. there was a peak in the hourly density curve and a peak in the accident curve. However, it is to be noted that there was another peak in the accident curve at 1 a.m., or when the traffic curve was descending into a trough of minimum density. Obviously a preponderance of drunken-driving accidents occurred at this time in the morning. This was proved further by segregating those accidents that involved drinking.

The remedy in this case lies with the enforcement arm. Further inquiry brought to light the fact that the motor patrol coverage during the peak hour of accidents was only partial (Fig. 7), particularly during the secondary peak at 1 a.m. The coverage on this section of highway therefore should be changed or increased so that adequate patrol would be assured during peak accident hours.

CASE NO. 3.—PRESCRIBING FOR A DANGEROUS ROUTE

Still another case that often arises is partially summarized in Table 3. It will be noted here that 64% of the accidents are rear-end type and 57% of the total number are between passenger cars and trucks. These are the outstanding indicators of this case.

TABLE 3.—SUMMARY OF ACCIDENT DATA FOR CASE 3

Description	For This Location		State-wide percentage	Description	For This Location		State-wide percentage
	No. of accidents	%			No. of accidents	%	
Two or More Cars:				Type:			
Passenger car vs. passenger car	31	41	64.87	Intersection	0	0	29.56
Passenger car vs. truck	43	57	15.18	Approaching	25	33	42.88
Truck vs. truck	2	2	1.23	Overtaking	51	67	27.56
Single Car:				Overtaking Breakdown:			
Passenger	14	70	83.80	Miscellaneous (parked car, etc.)	5	9	29.61
Truck	6	30	4.26	Rear end	32	64	44.87
				Sideswipe	14	27	25.52

A short field observation established the fact that this section of highway is a two-lane road with sustained 6% grades, which slow truck traffic down to a comparatively low speed. The passenger traffic is forced to adopt this low speed for long distances because of the lack of safe passing sight distance. The layout of this section is shown in Fig. 1(*c*) with the position of accidents spotted for reference. It is noted at once that the accidents are "piled up" in those sections that are on curves, with a much smaller number on the tangents.

These data suggest that possibly a group of passenger cars are forced to stay behind a slow-moving truck until a driver becomes impatient enough to attempt to pass even without sufficient sight distance. Proceeding on this theory, it appears that possibly the differential in speed between passenger cars and trucks may account for the high percentage of rear-end accidents. This is borne out further by a study of the relative hourly density of trucks and passenger cars (Fig. 8). Therefore, the main line of investigation might well proceed along the line of ascertaining the relation of speeds between trucks and passenger cars and the effect of congestion on this factor.

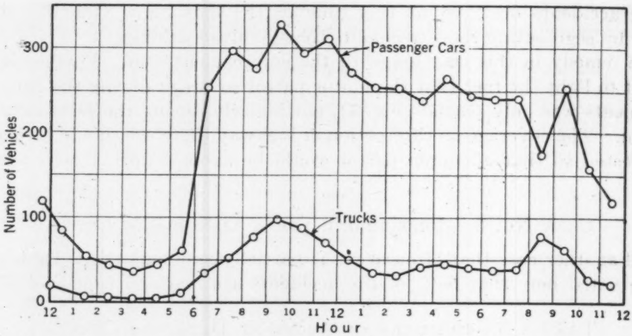

FIG. 8.—PLOT OF TRAFFIC COUNT, CASE 3

To determine the effect of the highway structure and surrounding terrain on the speed of traffic, it is first in order to collect speed data throughout the section, taken close enough together to show the variation in speed, but not taken where congestion exists. The speed, as shown by free-flowing traffic, is the criterion sought. Thus the critical speeds may be plotted on a profile (Fig. 9) and a "virtual speed profile" constructed.

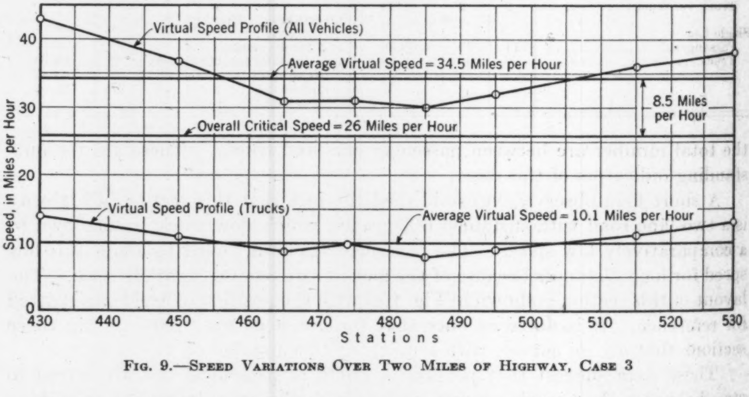

FIG. 9.—SPEED VARIATIONS OVER TWO MILES OF HIGHWAY, CASE 3

The next step is to ascertain the average "over-all" speed, which is the normal speed over this piece of road including time lost by congestion. By plotting a sufficient number of points the usual speed curve is obtained from which a critical speed of 26 miles per hr is selected as the representative safe speed, including time lost by congestion for this section. This has been plotted on the virtual speed profile and indicates that there is a loss of 8.5 miles per hr from the average virtual speed.

A study of the profile indicates those points that will bear further investigation in order that methods may be devised to raise the over-all speed to approach that of the virtual speed. This part of the study consists in the main of separating the slow-speed vehicles from the fast by either additional lanes or a separate truck road. The preponderance of rear-end accidents is added incentive toward separation based on speed; hence, in this case uniformity of speed and safety go "hand in hand."

The average loss of time over this two-mile section was calculated from the data to be 1.08 min or a total over a year's time of 2,222,000 min. This fact has an economic use in selecting the type of design used in the remedy. Various values per minute of lost time have been computed; for example, $0.0075 for passenger cars and $0.0147 for an average truck, in one instance,[2] and $0.01 for passenger cars and $0.0245 for heavy trucks, in another.[3] Using for this example the value of one cent per lost minute, the total loss capitalized at 5% would possibly warrant the expenditure of $444,400 for improvement. The proper value to be assigned to the saving of a minute of time is a matter to be decided on in each particular case.

TRAFFIC DATA FOR DESIGN

Design might be briefly described as the accommodation of structure to facts. Therefore, it is logical to presume that all facts are at hand prior to design. Heretofore only scant attention has been paid to traffic facts, as the highway engineer has been engrossed in the immediate problem of providing smooth, dustless roads at a rate consistent with the availability of money. The demand has been ever greater than the supply of funds. Only in late years has he paused for an instant to realize that the very element of his transportation problem—traffic—for which he has been building roads has not only kept up with the rate of production but has so far exceeded it as to create a problem of its own. Fundamental to design is knowledge of the traffic that will use the structure; therefore all traffic facts possible should be gathered for use in design.

Geographical facts are provided by the survey parties, giving the contour of the ground over which the line is laid, the drainage scheme, topographical data, and soil conditions. The laboratory provides facts concerning the materials—their strength, life, and other physical properties. Legal advisers and right-of-way agents determine facts affecting property rights. All these data combined with the engineer's experience form the foundation for his design of a structure to carry the vehicles of motor transportation; but what of the facts surrounding the use of those vehicles on the completed highway?

Securing and analyzing these facts are within the province of the traffic engineer. Inasmuch as this phase of highway engineering has but recently received recognition, traffic data and their relation to design are still in the first stages of evolution. As more thought is given to this subject, so the field will expand and more and better information will be demanded and obtained; and its analysis will be more definite. Those facts that are readily available at present and have importance in design will now be discussed.

---

[2] "Highway Economics," by Sigvald Johannesson, M. Am. Soc. C. E., 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1931.

[3] "The Economics of Highway Planning," by C. B. McCullough, M. Am. Soc. C. E., and John Beakey, *Technical Bulletin No. 7*, Oregon State Highway Dept.

A volume count probably stands first in importance, as the number of vehicles that pass a given point in a certain length of time determines not only the economics of the improvement but the width of lanes and shoulders, the number of lanes and the character of the intersections. A volume count also covers the type of vehicle, the number of passengers—in short, the numerical flow with or without the relative percentages of predetermined subdivisions of type. It is important when making a volume count to have definite knowledge of the use to which that count is to be put in order to gather all necessary data and at the same time to avoid the collection of a mass of information that may be of no value.

The classification of vehicles is of vital importance to the designer if he is to correlate his design to the traffic to be borne. The major classes are usually passenger vehicles and trucks. Each has different elements to be taken into consideration. The ranges of speed are usually different. Their radii of turning are different as well as their wheel loads. Each element has a bearing on design features and the proportion of each classification will affect the design as a whole. Thus, a highway designed to carry trucks alone might conceivably be entirely different from one designed for passenger automobiles. Combine the two classes of vehicles in varying proportions and the design must accommodate the salient features of each classification.

Other types of vehicles would be handled in a similar manner, although their number is usually so small as to be of minor importance in design. The pedestrian, however, although not a vehicle, is a component part of the traffic stream whenever his actions or presence results in conflict. Rural areas are generally free of pedestrian problems except on the outskirts of cities; there it is often necessary to make a pedestrian, as well as a vehicle, count.

For the purpose of design, two elements of a traffic volume count are important. The first is total volume and the second is the peak-hour volume. Total volume for definite periods, such as 24 hr, per month, or yearly, enters into economic calculations. Fluctuations due to season activities sometimes may be handled best on a total monthly basis, especially for comparisons, whereas daily variations have assumed a variety of comparative volumes, based on 24 hr, 16 hr, daily average, daily weekday average, 6 a.m. to 6 p.m. average, and so on, according to the dictates of various engineers' policies. For mutual comparison of these various designated periods it is necessary to know the key hourly percentages to be applied.

The peak-hour traffic is usually the criterion for which the designer plans. By "peak hour" is meant that hour in the daily traffic pattern which most frequently carries the maximum volume during the day. It is the maximum density to be normally expected, yet does not represent unusual conditions prevalent only a few days out of the year—such as traffic for a football game or traffic temporarily detoured over the road in question. Peak-hour density should hold somewhat the same position in traffic engineering when applied to design as maximum stress does in structural engineering.

Successful design must take care of future as well as present conditions. Volumes and densities will change and the designer is obliged to forecast these changes as best he can. Projecting past experience ahead from present knowledge is well established procedure but needs careful manipulation.

In forecasting traffic trends, a straight projection often will lead to fantastic figures. An analysis of past trends will disclose many factors, apparently foreign to traffic, exerting an influence that causes the traffic curve to bend into a form not consistent with past records. Population trends, economic conditions, migration, and even weather conditions have an effect on traffic. In particular locations, public pressure for new roads, improvement of old roads, new industries, and better living facilities, as well as many other causes, are reflected in the traffic curve. For design purposes, the future peak-hour load should be given a great deal of thought and its selection should reflect not only the past trend but also all possible factors that can be estimated as having any effect in the future.

A corollary to volume count, and of importance to the designer, is a record of turning movement. Naturally applicable only at grade intersections, the percentage of total volume that leaves, enters, or crosses the main traffic stream is a definite index of turbulence within the stream. The larger the turning movement, for example, the greater must be the provisions of design to accommodate this factor with as little disturbance of the other traffic units as possible.

Many devices for accomplishing this have been designed and constructed. They range from simple traffic stripe markings to complicated "clover-leaf" intersections. The underlying factors that determine the degree to which an intersection should be improved rest on the total yearly volume for economic reasons; and on the turning and crossing movements, particularly during the peak hour, for traffic reasons. Delays also enter the study of intersection design and are capable of being determined and evaluated.

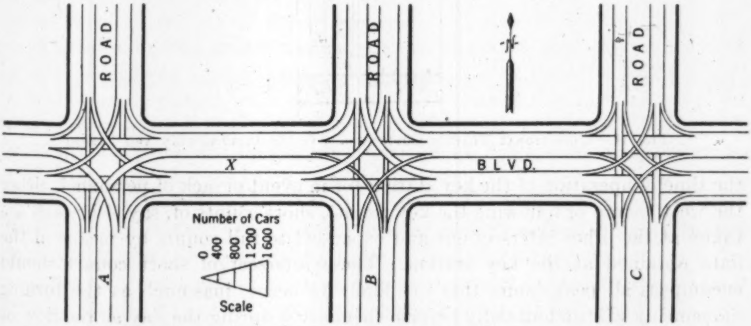

FIG. 10.—GRAPHICAL VOLUME CHART SHOWING PEAK-HOUR TURNING MOVEMENTS

Turning movements may be recorded in the same manner and at the same time that a volume count is made. The hourly percentage of turning movements follows a traffic pattern just as volume passing a point does. Hence, short counts may be expanded by use of key-station counts as a basis. A typical example of the application of volume and turning-movement counts may be seen best by reference to Fig. 10. Boulevard *X* is to be improved and the intersections of *A*, *B*, and *C* roads are also to be improved. It is necessary to ascertain the traffic flow throughout the proposed project and provide the engineer with a flow sheet for his design.

From observation and previous knowledge of the traffic in this vicinity it is decided to set up a key station at the intersection of *B* road and boulevard *X*. The counts consist of volume divided into their respective movements for each hour of the day. The volumes are further classified as to type of vehicles if necessary. The field sheets are then summarized as shown in Fig. 11. During

FIG. 11.—DIRECTIONAL TRAFFIC COUNT FOR A GIVEN INTERSECTION AND PERIOD

the time of operation of the key station (or in event of lack of personnel, either the week before or following the key count), short counts of, say, 4 hr each are taken at the other intersections and expanded to full counts by means of the data obtained at the key station. These intersection short counts should encompass all peak hours that are likely to occur, inasmuch as the turning movements will undoubtedly reverse themselves during the day as the flow of traffic is seldom continuous in one direction.

From these data it is easy to place the facts in graphic form by means of a "flow sheet" (Fig. 10) showing peak hourly flow. Average 24-hr daily flow, Sunday 24-hr flow, daily truck flow, or other relationships may be plotted in like manner.

Speed has lately become the common denominator for design, to which it appears reasonable and logical to correlate most other features. Combined with peak-hour volume and classification of vehicles, these three elements have been adopted by the American Association of State Highway Officials to designate the design limits of any road. Their use is not a matter of guesswork on the part of the engineer. Data to determine their value are collectable and a reasonable figure may be assigned, to which the various elements of a project may be so related that the whole will carry the designated volume at the design speed.

To obtain actual data for design speed, it is necessary to know what speeds are prevalent over the present route. In the case of new construction it is necessary to assume a design speed that will carry the expected traffic expeditiously over the proposed route. Both cases require knowledge of speeds that prudent drivers will use when the highways are completed.

Over longer projects and where special conditions may affect the speed, such additional speed checks should be taken to cover the project thoroughly or at least to permit the plotting of an accurate speed profile. Critical speed is usually accepted as a basis for design speed inasmuch as it represents the maximum speed which prudent drivers, usually 85% to 90%, consider safe. It seems reasonable to design for that percentage of traffic inasmuch as, no matter what design speed is used, a few will drive beyond that limit.

In lieu of information as to what might be expected in speed after the project is completed, speed checks can be taken on comparable roads and the information so obtained may be correlated to design conditions. What the future trend of automobile speeds will disclose is problematical, but past trends may be projected ahead and tempered by judgment. Speed checks taken in flat desert country with the latest type of improved surface, and very light traffic, indicate that the critical speed for automobile traffic will remain under 60 miles per hr. In such localities design speeds of 80 miles per hr and more are obtainable without much additional cost, but it is unlikely that the prudent motorist will exceed or even closely approach such speed as a common behavior.

The selection of a proper design speed contemplates that the engineer will provide a highway over which a goodly proportion of the total traffic will be able to pass safely at, or below such speed. This means that each feature of the road, such as width and number of lanes, shoulders, sight distance, intersections, and surface texture, will allow the same safe and orderly passage. Conversely, any section that does not come up to this criterion is a hazard. To select those factors that affect safe speed, it is only necessary to look at almost any neighboring road built some years ago and analyze each element of design. It is on this basis that speed serves as the common denominator for design.

Intimately connected with speed is the element of sight distance. This is usually divided into two parts—safe passing sight distance and safe non-passing sight distance, the latter being synonymous with safe stopping distance.

The many variables that must be assumed in applying any theoretical formula for obtaining passing sight distance leave the designer with no option but to use whatever values are offered until research has provided more data on which to base values. At present, the tentative values presented by the Design

Committee of the American Association of State Highway Officials are given in Table 4. The approximate formulas have been derived by the writer for "rule-of-thumb" use.

TABLE 4.—MINIMUM SIGHT DISTANCES FOR PASSING AND NON-PASSING

Design speed, in miles per hour (M.P.H.)	PASSING SIGHT DISTANCE, IN FT		NON-PASSING SIGHT DISTANCE, IN FT	
	By empiricism	By approximate formula, $(\text{M.P.H.})^2/1.6$	By empiricism	By approximate formula, $10\,(\text{M.P.H.}) - 100$
30	600	563	200	200
40	1,100	1,000	275	300
50	1,600	1,563	350	400
60	2,300	2,250	475	500
70	3,200	3,063	600	600

The application of sight distance to design may be divided into two phases, both interrelated: First, horizontal sight distance; and second, vertical sight distance. Horizontal sight distance is affected by such road elements as cut banks, trees, and structures, whereas vertical sight distance is affected by change in gradient which prevents full vision. The ultimate in design is unlimited sight distance, which obviously cannot always be attained. The minimum obtainable bears a direct relationship to safe speed, hence the use of data such as in Table 4. The two types of sight distance are often found at the same location and the minimum is isolated for governing use.

One factor that seems to have escaped the attention of designers is that traffic itself may introduce a blind area. This is particularly true where traffic volume rises to such a peak that an almost continuous stream of cars occupies a lane. In three-lane construction that embraces curvature, sufficient radius must be used to insure minimum sight distance when the outer lanes are fully occupied (Fig. 12).

In the use of sight distance, the designer must cope with an additional factor. Vertical curvature must permit a certain minimum sight distance; and the horizontal curvature, likewise, must be checked so that the driver's line of sight across an inside chord will not be obstructed by a cut bank, a structure, or traffic. To accomplish this calls for ingenuity.

In some cases it may be economy to widen from two or three lanes to a four-lane highway in order to take advantage of a non-passing sight distance inherent in such design as opposed to the longer passing sight distance necessary with fewer lanes. In two-lane construction in mountainous country, the designer is often confronted with a lack of safe passing distance commensurate with his design speed. In such locality advantage should be taken of every possibility to provide at reasonable cost areas of safe passing sight distance spaced at minimum distances apart. The non-passing areas should be "bunched" or localized, yet not be of such a length that an impatient driver will attempt an unsafe passing movement. A fine point in design is presented here, yet from an economic point of view an advantage may accrue in that lesser radii of curvature may be safely introduced in such non-passing areas.

To further protect the motorist, such non-passing areas should be double-striped, signed, or otherwise brought to his attention as areas throughout which it is dangerous to attempt to pass. In general, traffic should be fully warned as to what the road hazards are and should never be allowed to gain a false sense of security. It may seem paradoxical to build a new highway that contains a known hazard, yet no highway can ever be 100% safe nor is it always economically justifiable to build to an excessively high standard for limited traffic. A study of traffic conditions prior to relocation should dictate the amount of the expenditure. It is a sad commentary that highway engineers often allow minority pressure groups to do the dictating.

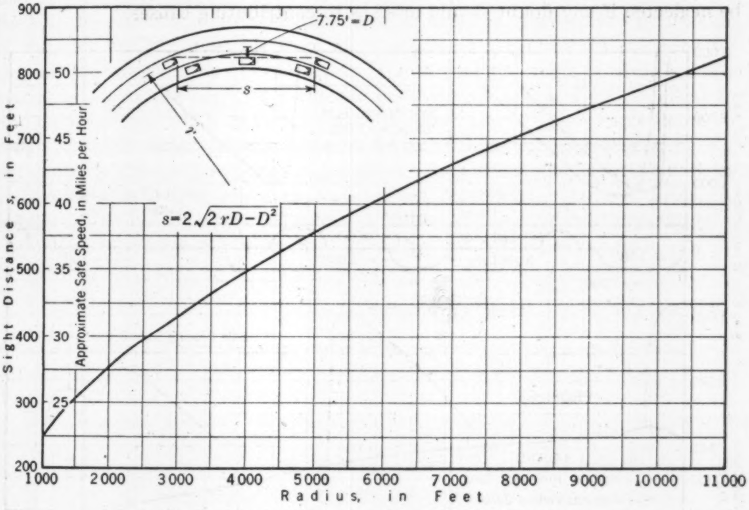

FIG. 12.—SIGHT DISTANCE ON 3-LANE CURVED HIGHWAY

To exemplify the question of sight distance and its relation to design, Fig. 13 presents a study made of a section of proposed relocation designed to a standard speed to be expected for that locality. It will be noted that both horizontal and vertical sight distance have been studied and safe passing sections indicated. Non-passing distance has been isolated and shown in cross hatching. Proper double stripes and signs would safeguard traffic throughout these areas.

Intersection design has received much comment in the technical press because of the innumerable methods proposed to minimize this most hazardous part of a highway. The underlying element is the proper appreciation of the behavior of traffic that will use such construction, as presented in five ways:

(1) Accident history of present intersection;
(2) Traffic flow sheet;

(3) Accident history of proposed design;

(4) Behavior study of present intersection so that proposed design will eliminate hazardous habits; and

(5) Comparative economy in time of passage through intersection using various traffic control devices.

The accident record and collision diagram of a grade intersection should receive careful consideration, as they indicate the intensity of need for change as well as the possible cause of hazard. Accident reports at intersections are much more likely to give a reliable cause than analysis of accidents occurring on the open road. However, the field investigation of driver habit should not be neglected if any doubt should arise as to contributing causes.

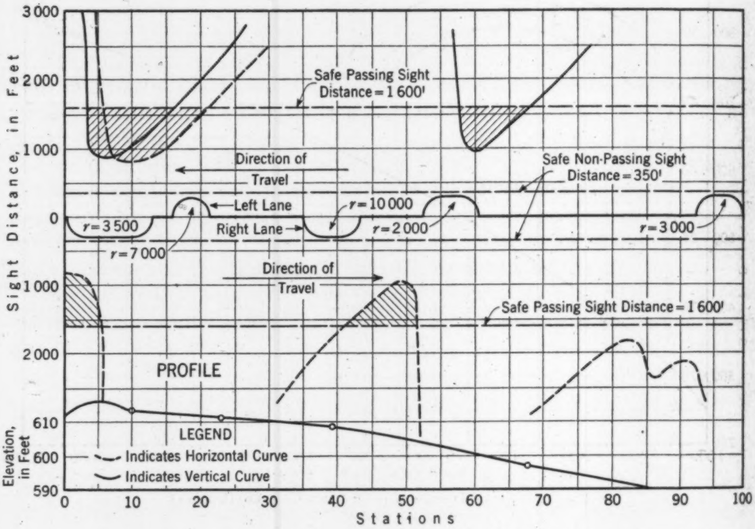

Fig. 13.—Study of Sight Distances on New Layout—Non-Passing Areas Hatched

The traffic flow sheet gives the fundamental factor for design requirements and should contain the maximum of information. For instance, if a secondary peak load with heavy turning movement obtains after dark, that fact may have a direct bearing on whether or not the crossing should be illuminated. If the accident history indicates an unusual number of accidents after dark on this movement, the designer would seldom hesitate to specify lighting in addition to special provision to otherwise safeguard the turning movement.

On the other hand, the expenditure of funds to provide a separate right turn when the flow sheet indicates practically none, is over-design. To fail to provide storage space for cars making left turns across heavy traffic is under-design that will lead to criticism as well as to a necessity to provide relief in some other manner.

The accident history of a constructed design, similar to that proposed and under comparable traffic, is invaluable. A very small change in detail may so affect the flow as to eliminate any danger prevailing in the constructed design. It may be that a certain turning movement or a peak volume may be handled in a slightly different manner or that surrounding conditions may be changed to eliminate potential hazards.

The angle of intersection has a direct bearing on design in that the angle of visibility of the driver is confined within relatively narrow limits from within his compartment. It is true that he can probably scan at least 270° of circumference by moving his head and shoulders, but experience indicates that he will barely move his eyes. For this reason, design should accommodate itself to the driver's habits and consideration must be given to the total angle of visibility easily obtainable from an average car. From data provided by General Motors Proving Ground, it was found that the angle of visibility is a maximum when the angle of incidence lies between 65° and 90° (normal to road approached) when approaching from the right.[4] These facts point to design that will cause one stream of traffic to impinge upon another at nearly right angles. The same is true where one traffic stream joins another flowing in the same direction, unless provision is made for acceleration lanes of sufficient length to allow both streams to become equalized as to speed and to commingle. Fig. 14 is an example of design that illustrates this problem in part.

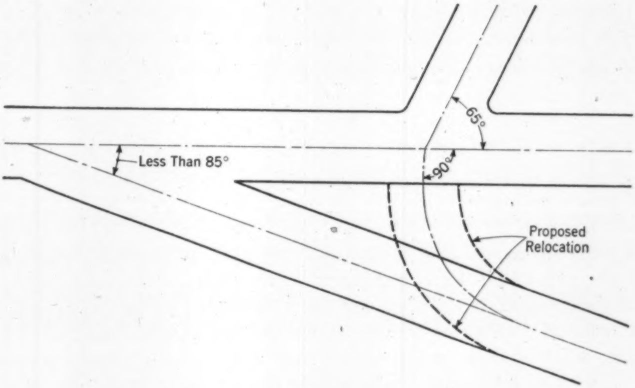

FIG. 14.—REVISION TO SOLVE VISIBILITY PROBLEM

The "loss-of-time" element in intersection design is of vital importance, for the efficiency of movement may be measured in terms of volume and time. The efficient utilization of an intersection is generally much lower than the intervening roadway, hence a proportionately larger amount of time and energy should be devoted to intersection design in order to decrease the over-all time loss and consequent discomfort to the motoring public. That the average motorist is willing to pay for his comfort is axiomatic.

---

[4] *Civil Engineering*, August, 1939, p. 494.

Accident records and their analysis should become a part of the fundamental knowledge of a modern highway designer. This is as necessary as knowing the rudiments of a mass diagram. The result of his work should be judged in the light of its ability to carry traffic safely and efficiently. Safety can only be judged by a man experienced in visualizing the effect of all attendant conditions upon the expected traffic stream and asking himself, "What type of accident will this condition impose?" Efficiency of flow must be judged in the same manner, yet both elements depend upon the designer's knowledge of the effect of his labors upon the major fundamental highway factor—traffic.

DISCUSSION

Charles E. Conover,[5] **M. Am. Soc. C. E.**—It is obviously impossible to bank the pavement adequately on curves of less than 500-ft or 600-ft radius, as the author so clearly indicates. Red flash signals on the right side of the pavement approaching the curve are of real value to the careful driver. The difficulty of providing signals that will curb the reckless driver, unless he sees clearly that his life is greatly in peril, is one that all highway engineers clearly recognize. Signs that have been placed along highways, where fatal accidents have occurred, stating the number killed at the location in question, seem to have a sobering effect on such drivers.

Transition curves, not as yet used to any great extent even on main highways, could be used to advantage on curves of less than 1,500-ft radius. The difficulty of securing the additional property in the shape of long, relatively narrow grooves is clearly recognized by the writer. The cost of such acquisition is always far greater than its real value even in undeveloped areas.

Highway pavement on curves should be wider than on tangents. So far as the writer has observed in traveling through many states east of the Mississippi River, it is not present practice to provide this necessary extra width.

The author refers to the accidents that have occurred on a particular section of two-lane highway with sustained 6% grades, which slow the truck traffic down to a comparatively low speed. He shows that accidents are "piled up" in sections that are on curves, with lack of safe passing distances, due largely to impatient drivers of light cars trying to pass the heavy slow trucks. The remedy is not to widen the pavement, but rather to make it obligatory for trucks to have engines powerful enough and so geared that they can maintain the speed of a passenger car. Rear-end collisions with trucks would lose much of their danger if the bumpers were arranged to be at the same elevation as the bumpers of pleasure cars. In other words, car design and truck design are not of less importance in the solution of the accident problem than highway design. Much has been done along this line since 1930, at least within and adjacent to the so-called metropolitan (New York) area.

By Fig. 10, the author portrays vividly the elements of danger always present at crossings, especially in the case of cars making left turns. In urban areas, left turns are often prohibited, and cars are forced, by right turns, to traverse an entire city block in order to accomplish the purpose of a left turn. This affords considerable relief to traffic at very busy intersections. On rural highways, however, the distances usually to be traversed by making right turns around a block, as a substitute for direct left turns, are so great that they compel the making of the left turn as a practical necessity.

At crossings where the traffic on one of the highways is heavy and that on the other is light, a very considerable reduction in the hazards due to such crossings has been effected in many locations adjacent to New York City by installing signal lights so arranged that the red light is set to be normally against the highway with light traffic. A bar is placed transversely in the pavement of the light traffic highway a short distance back of the intersection, electrically connected with the signal light in such a manner that a vehicle passing over it changes the light for that highway for a limited period, the duration of which depends on usual traffic conditions at the intersection.

STEPHEN E. BUTTERFIELD,[6] ASSOC. M. AM. SOC. C. E.—The use of certain corrective engineering techniques to aid in the modernization of existing highways is a practice which to date has been used by a limited number of the more progressive state highway departments. From the point of view of more efficient highway usage, either in terms of accident reduction or increased roadway and intersection capacity, this practice is one that might be used to advantage to a far greater extent. Because many state highway departments are now (1941) faced with curtailed operating revenues, due either to the diversion of gasoline tax moneys or to national defense restrictions in the sale of gasoline, many thousands of miles of antiquated highways must be made to serve as best they may for some years to come. With this the case, it will be necessary for many states to revamp certain of their older highways by the use of any or all of the corrective techniques known to traffic engineers.

As clearly outlined by Mr. Harris, one of the first steps in such a program is the detection of the points of greatest hazard by means of accident records. With the application of the correct treatment to each point of hazard, a sound approach is afforded for a program of selective remedial measures. In applying this technique to several specific examples, the author has indicated how gratifying may be the results of such a selective procedure.

Closely akin to those points of hazard that are revealed by accident records are other points of secondary hazard which are not as easily recognized. They result in congestion and frequently cause accidents, but they do not always appear in the form of such familiar bottlenecks as narrow pavements, bridges, or underpasses. However, under conditions of fairly heavy volumes of traffic, they soon become evident. Frequently these bottlenecks may be intersections of types which are unable to adequately handle even the average volumes of traffic which pour into them for interchange. Thus it is that the capacity (and, therefore, the efficient use) of a roadway may depend almost exclusively upon the frequency and capacity of its interchanges. If this is the case, the solution obviously lies in remodeling the offending intersections. Progressive remedial steps are: The construction of additional turning lanes, channelizing islands, traffic signals, or clover-leaf grade separations.

An invaluable tool in gaging the efficiency of a highway system is the "speed and delay study." Mr. Harris has touched on this subject in his consideration of over-all speeds in Case No. 3. From a study of the speed profiles the points of congestion can be located readily and accurately. By the use of these data the proper corrective treatment can be applied to those specific locations, and only those locations, which are at fault.

The author states that in applying traffic engineering to rural highways the most outstanding feature that needs correction is the present structure, which must be made safe for existing traffic. Unfortunately, some state highway engineers, lacking the essential basic facts concerning points of congestion and locations of accidents, have felt that there is little or no salvage in an older roadway structure. Therefore, depending upon the funds available, a particular stretch of highway that is known to be unsatisfactory for economic transportation is either completely rebuilt or postponed for possible inclusion in the reconstruction program at some later date. Would it not be a wiser procedure, if only limited funds are available, to modernize the old highway in such a way that it may serve fairly efficiently for the additional period? This cost might be almost insignificant compared to the cost of complete reconstruction.

---

[6] Traffic Engr., State Highway Dept., Hartford, Conn.

As stated by Mr. Harris, the full use of all available traffic data is essential in order to design a highway that functionally fulfils its sole purpose of providing efficient transportation. The successful highway designer must not only interpret traffic data in terms of present conditions, but he must look into the future. He must boldly appraise and carefully estimate the demands that traffic will make on the proposed highway twenty or even thirty years hence. The design of a highway for current operating highway speeds may result in the construction of a highway already antiquated at the time of its completion.

NATHAN CHERNIACK,[7] **ASSOC. M. AM. SOC. C. E.**—Mr. Harris' paper serves to re-emphasize this point: That in the modernization of existing highway facilities, and in the design of new ones, there is a need for the engineer to adopt a "demand" point of view. This means that the engineer should regard a highway, first, as a facility for regular use by human beings operating machines over its surface for the purpose of traveling between given origins and destinations safely, expeditiously, comfortably, and conveniently; and secondly, as an engineering structure designed to carry specified loads and constructed with definite structural materials. A highway that cannot, at once, satisfy the "demand" specifications is a poor engineering structure, and serves constantly to reveal to the traveling public a disparaging reflection of engineering ability, irrespective of the fact that the engineer may not be to blame for conditions encountered.

Mr. Harris touches only lightly on the subject of economic justification of highway facilities. Where he does, however, he reflects the orthodox theory of economic justification—namely, that reduced highway and vehicle operating costs justify the magnitude of a highway improvement. This theory can stand drastic revision. For example, under "Case No. 3.—Prescription for a Dangerous Route" he states:

> "The average loss of time over this two-mile section was calculated from the data to be 1.08 min or a total over a year's time of 2,222,000 min. * * * Using for this example the value of one cent per lost minute, the total loss capitalized at 5% would possibly warrant the expenditure of $444,400 for improvement."

There seems to be something basically wrong with a statement that a saving of a minute by each vehicle might support a $445,000 improvement.

---

[7] Economist, The Port of New York Authority, New York, N. Y.

In the case of a truck, a minute saved does not necessarily mean a penny or two "saved." There is no saving, for example, in the portion representing fixed costs (taxes, insurance, etc.). These items have been paid for, in advance, and there are no rebates. Truck time saved does have value, but only if such time is substantial and can be utilized effectively. What could a truck operator do with a minute saved?

On the other hand, passenger-car time costs much less than truck time. In fact, in most cases it has no commercial cost whatever. Then again, car operating costs may sometimes prove to be higher, because of greater road distances and higher speeds on improved or new highways than on alternate older routes. All of these facts would tend to reduce the expenditures that could be justified for improved or new highways. Despite these facts, however, the experiences of toll highway facilities indicate that, as between a modern vehicular tunnel with a higher toll and alternate antiquated ferries, for example, or as between a modern toll bridge or toll highway and a congested "free" bridge or highway, a substantial group of passenger-car motorists are paying something extra, in tolls, for the privelege of using superior facilities.

A realistic approach to highway economics would therefore recognize these facts: (1) That operators of trucks and buses are more interested in highway economies that would permit them to make more revenue trips (and incidentally increase operating costs) rather than in those that promise unrealistic "paper" reductions in operating costs; (2) that passenger-car motorists (especially around urban areas) are more interested in reducing the "wear and tear" on their nerves than on their cars; and (3) that well-designed highway facilities can offer travelers positive "new" values, such as speed (consistent with safety), comfort, convenience, recreation, pleasure, and (again, especially in urban areas) freedom from the irritations and annoyances of the older hazardous and congested alternate highways controlled by traffic lights. In studies of the economic justification of modern highways, anticipated time savings may be used as indexes of these "new" values. Usually, however, they are largely neglected because they are not readily measurable.

To determine these "new" values, which, in many cases, overshadow doubtful anticipated operating cost reductions, requires the measurement of differences in the nervous energy used in traversing existing traffic-light-controlled streets and highways, on the one hand, and parkways, expressways, and freeways, on the other. Possibly this may be accomplished by means of portable instruments indicating the differences in the blood pressure under which drivers operate under different highway conditions. As Mr. Harris states in his "Introduction," "Traffic psychology is complex and as yet unsolved. * * * This type of research should be undertaken." Such research apparently may not come within the field of engineering or economics, but it would be highly fruitful and would throw a flood of light on the economic aspects of highway design.

Park H. Martin,[8] M. Am. Soc. C. E.—Engineering terminology should be specific, and not subject to several interpretations. The use of the word

---

[8] Planning Engr., Allegheny County Planning Commission, Pittsburgh, Pa.

"rural" in the title and body of this paper has caused the writer to speculate at some length as to what the author intended to imply. After careful study, the writer concluded that the term "rural" as used embraced any and all types of highways lying outside of, or beyond, urban centers.

Expression of opinion was sought by the writer from half a dozen engineers of experience in highway work, as to their interpretation of the term "rural highway." Without exception the opinion expressed was that rural highways meant highways extending through rural areas, with very limited vehicular travel.

It seems ridiculous that a term used so much in highway engineering should have so indefinite a meaning. In general, "rural" has been used as defining a certain class of highways. Highway classification terms are not uniform; nor do the words used by one department mean the same when used by another. Several illustrations picked at random follow: From the State of Oregon System—

System	Types
R-1	Rural arterials
R-2	Rural general use laterals
R-3	Rural land service ways
U-1	Urban arterials
U-2	Urban general use laterals
U-3	Urban land service ways

The 1940 report of the State Wide Planning Survey of the Maryland State Road Commission states on page XVII, "This plan for centralization of authority and responsibility contemplates the grouping of all public rural roads into three systems for administration purposes: (*a*) State Primary Road System, (*b*) State Secondary Road System, (*c*) Local or Land Service Roads."

In the State of Pennsylvania a somewhat different classification exists. In 1911, by an Act of the Legislature, a State System of Highways was created. Main roads connecting county seats, cities, and boroughs were taken over as state highways. About 12,000 miles of highway were involved. In 1931, by an additional Legislature enactment, 20,000 miles of highway were added to the system. The 20,000 miles of new highway was designated as the "Rural Route System," the original 12,000 miles being commonly called the "Primary System." The justification given for taking over 20,000 miles of new highway was "To take the farmer out of the mud." Since farmers live in rural areas the term "rural" was given to the addition. Many of the roads taken over were not rural in traffic or service and are less so now, but the term still applies. Conversely many were rural in character and service, and still remain so.

Traffic data made public by the Pennsylvania Department of Highways from an eighteen-county traffic study involving 8,584 miles of road are as follows:

Vehicles per day	Miles of road
<50	1,447
50–99	1,247
100–149	837
150–199	564

The foregoing shows that 4,095 miles of the 8,584 miles investigated carry less than 200 vehicles per day, and the remainder, of course, greater traffic.

The writer is of the opinion that the term "rural highway" is not a proper engineering designation and that highway engineers should have a uniform classification nomenclature to designate the several different classes of highways. The basis for determining the terminology to be applied is debatable. The writer ventures to recommend that traffic volumes and traffic use be the foundation for the classification and terminology. This recommendation is made notwithstanding the opinion of some highway engineers that traffic records cannot be used to divide or classify highway systems. For example, M. R. Keefe, M. Am. Soc. C. E., has written:[9]

> "On studying our traffic records it soon becomes apparent that one cannot divide the existing system into existing primary and secondary roads on the basis of traffic. On many roads one section will be carrying light traffic, 100 to 150 vehicles per day, while on another adjoining section the count may run 750 to 1,000 per day."

The author implies that rural traffic is different from city or urban traffic. The large majority of drivers on rural highways (the term hereinafter used in the largest sense) are urban residents and drivers. The average driving speed is undoubtedly higher, but otherwise the driving habits are not much different on rural highways than upon urban highways and streets.

The author seems a bit inconsistent in his discussion of traffic behavior. Quoting from the "Introduction":

> "By analyzing traffic action, traffic behavior can be determined and evaluated. Roads should be built accordingly; hence, it seems reasonable to expect a road design that will accommodate that behavior which is normal to those who drive with prudence."

In the next paragraph, however, he states:

> "Doubtless, driving habits can be changed by education and by enforcement, but more probably can be accomplished by natural regulation resulting from properly designed highways which accommodate themselves to reasonable existing traffic patterns * * *."

It is true that drivers as a class do have certain uniform habits. For instance, they will not drive close to a curb on an open highway, very many spiralize curves of their own accord, but the engineer must plan from sound engineering principles and not from drivers' changing whims or habits.

The most outstanding project of modern highway engineering with which the writer is familiar and in which has been incorporated every known principle of approved highway design, is the Pennsylvania Turnpike. Yet, notwithstanding the care in planning and expenditures made, drivers will "crack up." It is evident that a wholly foolproof road can never be designed and built.

Four-lane divided highways are given as an example of engineering that will eliminate head-on collision. Several years ago the Pennsylvania State Department of Highways rebuilt a part of the Bigelow Boulevard in the City of Pittsburgh as a freeway with 12-ft lanes, a division strip being protected by curbs with a 10-in. reveal. Experience has shown that it is a rather common occurrence for cars to crash over the curb and wreck themselves on light standards set in the dividing space. The irony of one of the wrecks was that it was a police squad car. This is not to recommend that the divider should be eliminated, but rather to re-emphasize the personal element in driving.

---

[9] "The Indiana Secondary Road Program," by M. R. Keefe, *American Highway*, October, 1936.

The author illustrates and mentions the use of photography as an aid in traffic studies. This suggestion is excellent and its use is desirable in various ways, one of which could be the study, by means of moving pictures, of merging traffic behavior.

Another commendable point made by the author is the observation of traffic under varying conditions of light and weather. The writer has long been impressed by the failure of traffic engineers and designing engineers to give more consideration to night visibility on a highway. Traffic islands in many instances serve a useful purpose, particularly when lighted. On rural highways, they may become points of hazard, due to poor visibility at night. Attempts to direct traffic by channelization which involve complicated openings and confusion points should be avoided, particularly when such points are not lighted.

At another place the traffic engineer, or some maintenance crew, may have failed in the placing of directional and speed signs. This criticism refers particularly to older rural highways of poor alinement. The writer has observed many signs that are visible in daylight driving, but are either invisible or only partly visible at night. This is generally the result of improper placing.

The writer is of the opinion that the placement of traffic signs should be studied in the field at night, as well as by day. The proper "signing" of highways, particularly those routes which have poor alinement, and for which funds are not available for reconstruction, is highly important.

The night accident record on rural highways is very bad, as testified[10] by Kirk M. Reid, of the General Electric Company:

> "What are the facts as to the relative day and night hazards on our rural highways? The statistics gathered by your departments show that from three-quarters to four-fifths of the total 24 hour traffic is by day, and yet almost half the non-fatal accidents and over half the fatal accidents occur during the period of dusk and darkness. Hence the average accident hazard per vehicle mile at night is three to four times that by day. And the fatality rate per accident is 64 percent greater at night."

A study of the proper placing of signs that are visible for night driving seems to be a field which needs more attention from traffic engineers. The author has discussed this subject, somewhat, in his example of study involving a curve reduction illustrated in Fig. 6. The result is the recommendation that the curve be reduced with a radius of 644 ft for a speed of 50 miles per hr. This is all very good, but it should be remembered that there are thousands of such curves which probably cannot be corrected because of lack of funds. Why not place a directional curve sign at the proper place at the curve approach and mark on the sign the safe speed for the curve, such as "Speed, 35 Miles"? The distance that the sign should be placed from the point of curvature should not be less than the distance required to brake the speed of the approaching car from what would be the safe speed of the car in the tangent down to the safe speed recommended for the curve. There is also one additional factor to be considered in setting the safe speed to negotiate a curve: On a two-lane highway the speed should not exceed the distance required to bring a car to a stop if an obstruction, such as a stalled car, is on the road in the path of the moving car.

---

[10] "The Night Accident Hazard," by Kirk M. Reid, *American Highways*, January, 1936, p. 16.

In the case of the example cited in Fig. 6, the safe sight distance will be less than 250 ft and the safe speed should be less than 50 miles per hr for the corrected curve. The critical speed is sometimes assumed to be about 50% greater than the safe operating speed.

The importance of traffic data for design cannot be stressed too much. Many designers give no thought to this important relationship, if left to themselves. The writer cannot see how there can be a rational design of a highway without all the known facts of traffic being considered. The writer has in mind one project in which the designers proceeded without traffic figures. When those in charge of design were asked for their traffic data, it was found that they had not considered any. A complete origin and destination survey was made and the original preliminary plans were discarded entirely.

The peak-hour traffic is undoubtedly the criterion for which the designer plans. Daily volumes are interesting and of value in presenting the economics of a problem, but the peak-hour load is the controlling factor in design.

Forecasting is interesting but sometimes rather hazardous. Notwithstanding the uncertainties sometimes involved, it must be done. Forecasting the future of a highway may sometimes result in recommendations for a new highway rather than heavy expenditures for the reconstruction of an existing highway. For example, state Route No. 19 is the main route leading north from Pittsburgh. Outside the city limits the road passes, for four miles, through rather populated suburban areas. On one particular section the alinement is poor. For some time there has been considerable agitation to correct this condition by the construction of a bridge. This would entail an expenditure of several million dollars resulting in a considerably depressing effect upon adjacent property values. The construction of a new four-lane divided highway through undeveloped farming land about one mile east was decided to be the better plan. The construction of the new highway (at a cost only slightly more than the cost of the proposed bridge) affords two routes for some distance north of the city, with considerable relief to the existing traffic load on Route No. 19.

The lack of adequate parallel roads, particularly detour routes, in times of construction and repairs, is becoming more apparent and more serious as traffic volumes increase. Minor roads in the vicinity of main routes should always be considered in the light of available detour routes.

The writer cannot agree with the author when he states (see "Traffic Data for Design")—"To obtain actual data for design speed, it is necessary to know what speeds are prevalent over the present route." Maximum speed limits on rural highways are fixed by law. They may vary from 45 to 55 miles per hr. The vast majority of drivers, even under the best conditions, cannot drive safely at a speed greater than 60 miles per hr. It is assumed that the case the author has in mind involves the reconstruction of the highway. Since the highway is to be modernized, it would seem to the writer that the design should provide for the safe legal speed, which in turn would permit a higher critical speed. Unless the highway is a freeway, the design speed should not exceed 60 miles per hr. Since internal-stream friction (the conflict of faster and slower traffic in the same direction) is the cause of the greatest percentage of accidents, it does not seem wise that greater speeds than legal limits should be encouraged.

Minimum sight distances for passing and non-passing are now well determined and accepted in standard practice. The writer, personally, will remain a critic of three-lane highways. Economically, as well as from the standpoint of safety, they do not appear sound. The only exception that may be noted is in the case of truck lanes in mountainous areas. Joseph Barnett, M. Am. Soc. C. E., has presented[11] an interesting and instructive treatment of highway intersections. When funds are not available for separation devices this phase of rural highways is highly important.

Too much stress cannot be placed on the angle of visibility, not only at intersections but at accelerating traffic lanes. The writer has not been convinced of the desirability of expecting a driver to attempt to look over his left shoulder at a very flat angle in merging into high-speed traffic from an accelerating lane.

In 1941 the City of Pittsburgh, County of Allegheny, and Pennsylvania State Department of Highways completed a grade separation in the city of a street and Bigelow Boulevard. A merging traffic lane is brought into the Boulevard by a curve, the deflection angle of the access lane with the Boulevard being 25°. The radius of the curve between the access lane and the Boulevard is 588 ft. Speed on the Boulevard is about 45 miles per hr. Those who have observed its operation have been very much impressed by the speed and ease with which the traffic merges.

The writer agrees with the author (see "Traffic Data for Design") in that: "The angle of intersection has a direct bearing on design in that the angle of visibility of the driver is confined within relatively narrow limits from within his compartment."

In presenting the subject of relationship of traffic engineering to highway design, the author has performed a service for highway engineers. The writer is hopeful that his discussion of highway classification terminology may result in some terminology more acceptable than the word "rural."

Charles M. Noble,[12] M. Am. Soc. C. E.—The modern attitude of the more progressive group of highway engineers is reflected in this paper in that the functional character of the highway in relation to the operation of the vehicle and the characteristics of the driver is stressed. The writer is strongly sympathetic to this view and therefore wishes to strengthen that type of thinking and indorse the paper.

It is encouraging to note the reference to research in traffic (driver) psychology, for it is believed[13] that such research will yield substantial dividends in transportation efficiency and accident reduction by pointing the way to correct design.

[13] *Proceedings*, Highway Research Board, 1937, p. 246.

In addition to the principle enunciated by the author (that it may be advisable to introduce into the highway structure a physical change that will convert one type of accident into another less dangerous), it is also quite possible for the designer of a new facility to visualize many accident possibilities in advance, during the design process, and to arrange the design in anticipation of such possibilities. This is illustrated in the case of the Pennsylvania Turnpike tunnels, where it was necessary to converge from two lanes into one lane on entering, and the possibility of a skid or other mishap occurring in the confined roadway in front of the portals was anticipated. With a conventionally designed portal such a mishap, in many cases, would result in a direct collision with the immovable portal structure, generally with serious consequences. In the Turnpike design, a wall of the stepped type was projected out from the portal face, curving away from the roadway gradually until it disappeared into the bank of the approach cut. This wall was designed for the purpose of converting a direct impact accident into one of less serious character of the sliding type. Actual operation experience indicates that the walls are functioning with complete success, and many serious accidents have been averted by their use.

From the standpoint of transportation efficiency, the analysis by the author, utilizing a virtual speed profile to determine time losses, is valuable; for, although the average driver would be convinced immediately that an improvement should be made, it is often difficult to convince highway authorities, struggling with budgetary problems, of the necessity for improving part of an existing highway. The method illustrates the critical locations graphically and provides an economic argument that may be used to convince the authorities that funds should be authorized for remedial measures.

The author states (see heading "Traffic Data for Design") that "Design might be briefly described as the accommodation of structure to facts"; and

> "Only in late years has he [the highway engineer] paused for an instant to realize that the very element of his transportation problem—traffic—for which he has been building roads has not only kept up with the rate of production but has so far exceeded it as to create a problem of its own. Fundamental to design is knowledge of the traffic that will use the structure; therefore all traffic facts possible should be gathered for use in design."

He also states that "As more thought is given to this subject, so the field will expand and more and better information will be demanded and obtained; and its analysis will be more definite." All these statements should be applauded. Again the author goes to the heart of the modern traffic problem in the paragraph beginning "The peak-hour traffic is usually the criterion for which the designer plans."

With respect to the author's comments relative to design speed, it is pertinent to remark that, if too low a value for design speed is selected for the main routes, such highways may again become obsolete within a relatively short period (10 to 15 years), resulting in an economic loss, and the engineer may suffer embarrassment and possible loss in prestige in having to acknowledge the adoption of a shortsighted policy.

In closing, a word of caution should be interjected, for there is a tendency in some quarters to feel that engineering can solve all traffic problems, human and otherwise, and that enforcement can be relaxed when modern design is provided. Such is far from the case, as Mr. Harris recognizes clearly, and the writer wishes to emphasize the point that modern highway engineering and enforcement should function in unison.

Mr. Harris has covered his subject quite thoroughly as far as general principles are concerned, and very little can be added except as a matter of indorsement.

MISSOURI RIVER SLOPE AND SEDIMENT

By William Whipple, Jr.,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Samuel Shulits, Leo M. Odom, E. W. Lane, Elliott J. Dent, and William Whipple, Jr.

Synopsis

The project for the improvement of the Missouri River consists primarily of open-channel regulation, which contracts the natural channel in addition to materially changing its shape. A general description of the methods adopted is given, together with a quantitative summary of the effects of the improvement upon the length, slope, width, shape, discharge, velocity, and roughness coefficient of the natural stream between Rulo, Nebr., and Sioux City, Iowa. Data are supplied as to the bed and suspended sediment characteristics of the river, in both improved and unimproved sections. An analysis is presented of the applicability of various bed-load formulas, involving both competence and capacity, to the prediction of the future slope of the river; and results are compared with observations to date (1940) on completed sections of the river. It is generally concluded that: (1) Formulas involving competence will not give the answer to this particular problem; (2) the mean slope of the Missouri River eventually will decrease through the operation of the contraction works; and (3) the bed of the river will scour out progressively for some time to come.

Introduction

The improvement of the Missouri River consists of open-channel regulation of approximately the lower 760 miles of the river, with regulation of flows through the Fort Peck Reservoir (see Fig. 1). It has been prosecuted by the Corps of Engineers primarily in the interest of navigation since authorization by Congress in 1927 and 1935, but some work was done under earlier authorities dating back to 1876. Despite the magnitude of this project and the length of time since it was begun, comparatively little has been published regarding the hydraulic characteristics of the stream. As far as the writer is aware, this paper represents the first published compilation of the basic data from which

a prediction can be made of the ultimate effect of this improvement upon the hydraulic characteristics of the river. The principal phenomena involved are governed by channel erosion and deposition, and the present study is concerned mainly with the effect of the improvement works upon the competence and capacity of the stream and the probable effect of these changes upon its eventual slope. Data presented deal principally with the part of the river between Sioux City and Rulo, which is approximately the upper third of the improvement, but the results obtained should have some application to the lower sections of the river, as methods used have been generally similar.

GENERAL DESCRIPTION

A complete description of the Missouri River and its tributaries has been published in the "308 report" on the Missouri River.[2] Certain of the applicable basic data are summarized herein. The Missouri River (see Fig. 1) is about 2,470 miles long and drains an area of 529,000 sq miles. The headwaters of the Missouri River and some of its tributaries lie in the Rocky Mountain province, but the greater part of the drainage basin lies in the Great Plains province and the central lowlands. It is noteworthy that, within the area improved, the Missouri River runs through and over deposits of its own sediment, which fill an ancient valley much deeper than the present stream bed at all points. The river never strikes rock or other unerodible material except at occasional points where it approaches the adjoining bluff. The Missouri River experiences wide fluctuations in discharge. Fig. 2 shows the mean monthly runoff and the total annual runoff for the years 1929 to 1937, inclusive, at Omaha, Nebr. The year 1938 was excluded because in that year partial operation of Fort Peck Reservoir changed conditions materially from what they would naturally have been.

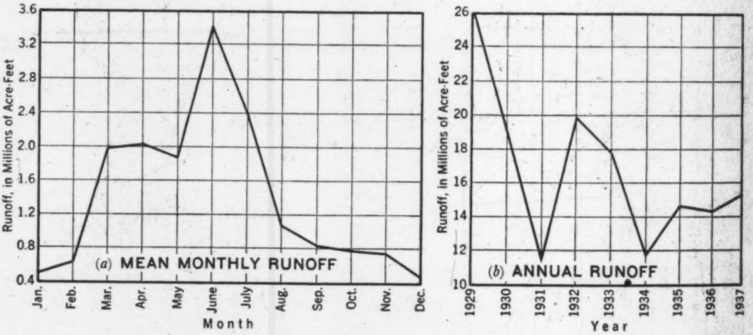

FIG. 2.—RUNOFF DATA, MISSOURI RIVER AT OMAHA, NEBR.

NATURE OF IMPROVEMENT

The improvement of the Missouri River was based upon the assumption that its average slope represented approximately a state of equilibrium under conditions existing at that time. The sediment content of the Missouri River is enormous, and if the existing slope had been insufficient to carry the average load for a long period of time the valley would have aggraded until an equilibrium slope was reached. On the other hand, it was obvious, from the many meandering oxbow lakes and the low banks, that below Sioux City the Missouri River was not in process of eroding a deeper channel. Although the river in its natural state is constantly varying its length and slope locally, these changes tend to counterbalance one another. It was known that during periods of prolonged drought the river generally silted up its bottom at all points, but these effects were not permanent. The net result of changes for several decades prior to the improvement program was an increase in slope; but insufficient information is available to determine whether, under conditions of nature, this increase would have continued, remained static, or reverted to its former level.

---

[2] *H. R. Doc. No. 238*, 73d Cong., 2d Session, February 5, 1934.

Method of Improvement.—The plan for improving the river includes a generally contracted channel in a series of easy curves rather than the succession of straight, wide reaches and involved meanders or abrupt changes in direction that had existed previously. The channel decided upon lay as far as possible within the existing channels of the river. Figs. 3 and 4 illustrate the improvement of one of the worst bends in the river.

When it is determined that the river is to be driven away from a given bank a system of permeable pile dikes is constructed, leading away from this bank. Such a system reduces the velocities in the areas selected for deposit and increases the velocities in the areas selected for the regulated channel. Consequently the water passing through the dikes deposits its heaviest sediment, while the water passing around the dikes, with the increased velocity, scours the bed and bank and erodes that part of the channel deeper and wider. As the erosion and deposition process continues, the dikes and areas between the dikes are silted in and the channel is secured.

As the channel, deflected by the completed dike system, erodes back to its designed alinement on the concave side, this bank is revetted and permanently stabilized, progressively as it reaches the designed alinement. The new bars formed on and over the dike system quickly grow up in willows, which further aid the silting process, so that, a few years after construction is initiated, the new channel is entirely within the designed alinement, with no obstruction to flow except the ends of a few dikes that have not yet completely silted in. Regular snagging operations keep the channels free from obstruction. In addition to the dikes and revetment, dredging is used to cut away deposits of clay or gumbo, to cut pilot channels through bars and islands, and to make cutoffs. The first such cutoff on the Missouri River was described in 1938 by Lt.-Col. W. M. Hoge.[3]

This river improvement, although constructed primarily in the interests of navigation, will operate to stabilize the banks of the Missouri River, permanently, thus protecting adjacent farm lands and other improvements that were formerly in continuous danger from the ever shifting channel. Since the Missouri River is a navigable waterway, land ownership extends only to the low-water line; and when all of an original holding has once been taken by

FIG. 4.—ASPINWALL BEND, 1938

erosion, the owner no longer holds a valid title, even though land might be reformed by accretion in the same place the following year. However, when the channel shifts from one side of the holding to the other through the process of avulsion, the title remains in the original owner and the jurisdiction in the original state. The shifts of the river channel have been so numerous and intricate that at many points land known originally to have been in Iowa now lies on the Nebraska bank, and vice versa; and for practically all land adjacent to the river no conclusive determination of either state or private boundaries has been possible.

Length.—The Missouri River originally flowed in a changing course involving successions of straight reaches, followed by abrupt and sometimes meandering bends. The improved river will have sinuous bends in place of all straight reaches but several of the worst bends will have been removed by cutoffs. There is considerable difficulty in stating the exact length and slope of a given part of the Missouri River, as the length of channel and the fall in the water surface between any two points varies not only from year to year but with the stage of the river. The length of the channel of the Missouri River between Rulo and Sioux City was measured (1890) as 270 miles. The length of the center line of the stabilized project channel between the same points will be 245.6 miles. In 1930, shortly before the improvement works began, the length of the thalweg at low stages was 251.8 miles, but at medium stages the length of the mean channel was almost the same as that of the present project channel.

Mean Slope.—With regard to the difference in water-surface elevations between two points on the river, the same difficulty exists, although the differences are proportionately smaller. The maximum water-surface elevation reached during the 1927 flood was about 240 ft higher at Sioux City than at Rulo, and for the 1938 flood, about 234 ft. However, a uniform low-water plane, established in 1938, shows a difference of 236 ft, which will be used as the average head available to the river between these two points. This corresponds to a mean slope of 0.96 ft per mile, at medium stages, as long as the head available remains unchanged.

Width.—The mean width of the project channel above Rulo will be 725 ft, with a maximum of 1,000 ft and a minimum of 700 ft. The latter will prevail throughout the greater part of this section of the river. The 1930 channel had minimums considerably less than 1,000 ft, a mean usable width of 3,650 ft, and a maximum width not easily measured because of the many islands, back-chutes, and low bars that are difficult to classify.

Shape.—It is obvious that major changes in shape and curvature of a river may greatly influence its regimen. The new project channel will be fairly uniform and relatively easy to classify and describe, but the old channel was so irregular in shape that it is difficult to present any idea of its hydraulic characteristics other than by a complete series of large-scale maps much too bulky for presentation in this paper. Back-chutes, split channels around islands, and small bars, with or without vegetation, were very numerous in the uncontrolled river, but it is difficult to describe this condition other than qualitatively and by the example afforded by Fig. 3, which covers only a very small part of the river.

Although the eventual slope of the Missouri River depends primarily upon its sediment-carrying characteristics, certain hydraulic conditions must be evaluated as a basis for the direct approach to the problem. When the improvement of this section of the Missouri River is completed, it will have contracted the channel to a uniform width, left the length unchanged, removed snags, eliminated split channels, generally changed the shape of the channel, substituted dikes and revetment for natural banks, and regulated natural flows through operation of Fort Peck Reservoir. These factors, and other factors, not part of the improvement, all have their effect upon the general hydraulic characteristics of the river, which in turn determine its sediment-carrying capacity; and these relationships are evaluated in this paper to the extent that the available data will permit.

GENERAL HYDRAULICS

Local Slope Variations.—The existence of a substantial uniformity in mean slope taken at various times must not be understood as implying a uniformity of slope over different parts of the river at any one time. Gages set at 5-mile intervals show very considerable variation. Studies of water-surface elevations at gages established at half-mile intervals or less, with precautions to avoid discrepancies due to superelevation, show very great local variation in slope. Even for fairly well stabilized parts of the river, local slopes still vary from less than 0.5 to more than 2.5 ft per mile. Moreover, a new profile taken at the same point a few weeks later may show considerable change.

A study of all available data sheds light on certain slope irregularities and leaves others not yet explainable. For example, two persistent steep slopes were identified as due to the presence of protruding ledge rock into the channel from the adjacent bluff. Some longer reaches, the slopes of which are greater than average at high water only, unquestionably demonstrate disturbing effects of excessively severe bends. In incompleted parts of the river certain slope deviations in both directions from the mean are known to be incidental to the improvement works, and therefore of temporary nature. Sufficient data have not been developed to show the extent of local steepening to be expected at crossings, partly because studies of this nature have not yet been made at extremely low stages and partly because of the presence of so many other disturbing influences of greater magnitude. The effects upon the slope of the Missouri River of the heavy bed load carried by the Platte River have previously been described in detail elsewhere.[4] These effects are of major importance and extend many miles down the river. As measured during the low water of 1930, the mean slope for 31 miles above the mouth of the Platte River was 0.74 ft per mile, and for 44 miles below that point it was 1.24 ft per mile. Locally, steep slopes are found at many points where back-chutes reenter the main stream at an angle, whether or not this occurs at a crossing. This is probably due to bar deposition in the main stream by the chute during times of high water. These half-mile gages have been set only on improved and partly improved reaches of the stream, but similar or greater variations are believed to exist in unimproved sections of the river.

---

[4] *H. R. Doc. No. 238*, 73d Cong., 2d Session, February 5, 1934, Appendix XV.

It is probable that the completed channel will always have certain slope irregularities, due to tributary influences, variations in shape, crossings, and irregularities in the transportation of bed load. However, disturbances at reentrant back-chutes will be eliminated. The extent of excessive slopes at crossings and bends will vary according to the number and severity of bends.

Comparison of Shape.—This study was based upon complete large-scale maps of 1930 and 1939, which show, respectively, conditions prior to any improvement in the section between Sioux City and Rulo and conditions of the present, including the adopted channel line. As a first step in classifying bends, lines were drawn on each map to show, as accurately as possible, the mean channel line of the river at medium stages throughout its length. For the improved channel this was taken to be the center of the project channel. For the maps of the unimproved river it was necessary to disregard small irregularities, and in the case of a split channel either to adopt a line intermediate between the two parts or to follow either one of the channels that was considered to be representative, in both length and curvature, of the river as a whole. Figs. 2 to 4 illustrate these lines for the reaches of the river concerned.

Although excess loss of energy in a bend is occasioned primarily by sharpness of curvature (measured by length of radius in the bend) it is also affected (particularly during overbank flow) by the total angle through which the river is turned. In the many bends of varying radii only the minimum radius in each bend was considered. The total angle through which the river is turned in a bend will be known herein (for lack of better nomenclature) as a "central angle." For convenience, all bends of less than 45° central angle were considered separately, as experience shows that, even during overbank flow, relatively little disturbance is caused by flow through bends of small central angle, despite radii less than those ordinarily desirable.

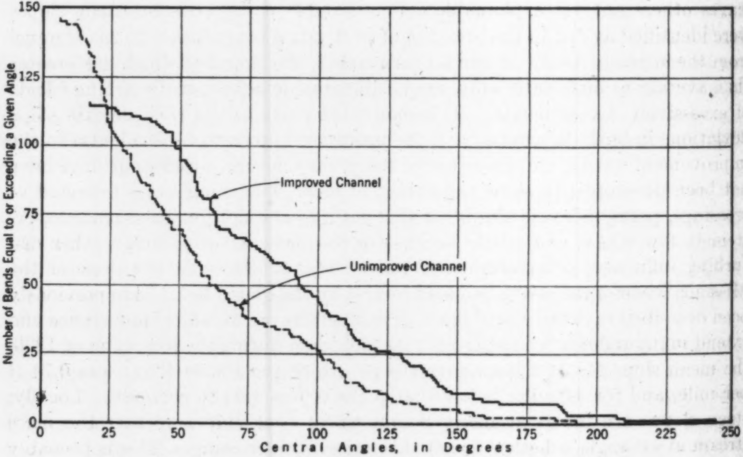

FIG. 5.—NUMBER OF RIVER BENDS CLASSIFIED BY THEIR CENTRAL ANGLES

Fig. 5 shows, for both the improved and the unimproved channel, the number of bends with central angles equal to or greater than any given curvature. These curves indicate that, apparently, the channel stabilization program has increased the number of bends of a central angle of 100° or more, but has made little change in the number of those between 45° and 100°. Actually the number of the longest meanders was reduced by cutoffs, but this fact is not apparent from Fig. 5 because many meanders in the unimproved river had to be classed as two or more successive bends in the same direction, separated by short reaches. Of bends of less than 45° central angle, the improved channel has only about one sixth as many as the unimproved channel. A summary of all data shows that in 1930 the medium-stage, unimproved channel had 147 bends, with a total angular curvature of 8,340°; whereas the future project channel is planned with 116 bends and a total angular curvature of 10,640°. At low stages in 1930, the thalweg had 269 bends with a total angular curvature of 14,286°.

The radii of curvature of the bends and general character of the meanderings of a river depend upon many factors, including the size of the stream, the slope of the valley, and the character of the sediment. The Mississippi River sweeps through its great curves in meanders of many thousands of feet radius, whereas some small stream flowing in curves of similar shape may have prevailing radii of only a few feet. On the section of the Missouri River considered in this study, experience has shown that, if otherwise properly designed, bends of 4,000 to 8,000 ft minimum radius are generally satisfactory and create no unusual hydraulic disturbance at any stages experienced in recent years. Straight reaches and bends with radii much greater than 8,000 ft have undesirable characteristics during low stages because of the excess number of crossings that may develop. These extra crossings introduce an extra sinuosity and impede the flow to that extent, besides being a hazard to navigation. On the other hand, bends of less than 4,000-ft radius, and particularly those of less than 3,000-ft radius, create excessive disturbance and turbulence in the river at bankful and overbank stages, and for this reason are no longer constructed. Fig. 6(*a*) shows that, of bends with central angles greater than 45°, the number with excessively sharp curvature has been greatly reduced by the channel improvement project. A separate study of bends of less than 45° central angle shows a similar result to have taken place, the bends of undesirable curvature in this class having been entirely eliminated by the improvement (see Fig 6(*b*)). If results for all bends in the river are combined, the number with less than any given radius is shown to have been decreased by the channel improvement.

It is believed that, considering solely the planimetric shape of the river, the final results of the improvement program will tend to increase the hydraulic efficiency of the river at all stages of bankful or less, due to reduction in sharp bends, irregular banks, excess crossings, and split channels. During overbank stages efficiency will tend to be somewhat less due to the greater curvature of the improved river, although promoted by the more regular shape, the reduction in the number of sharp bends, and other favorable factors. The relative importance of overbank stages as compared to lesser stages may be roughly estimated from the fact that from 1929 through 1937 (a subnormal period)

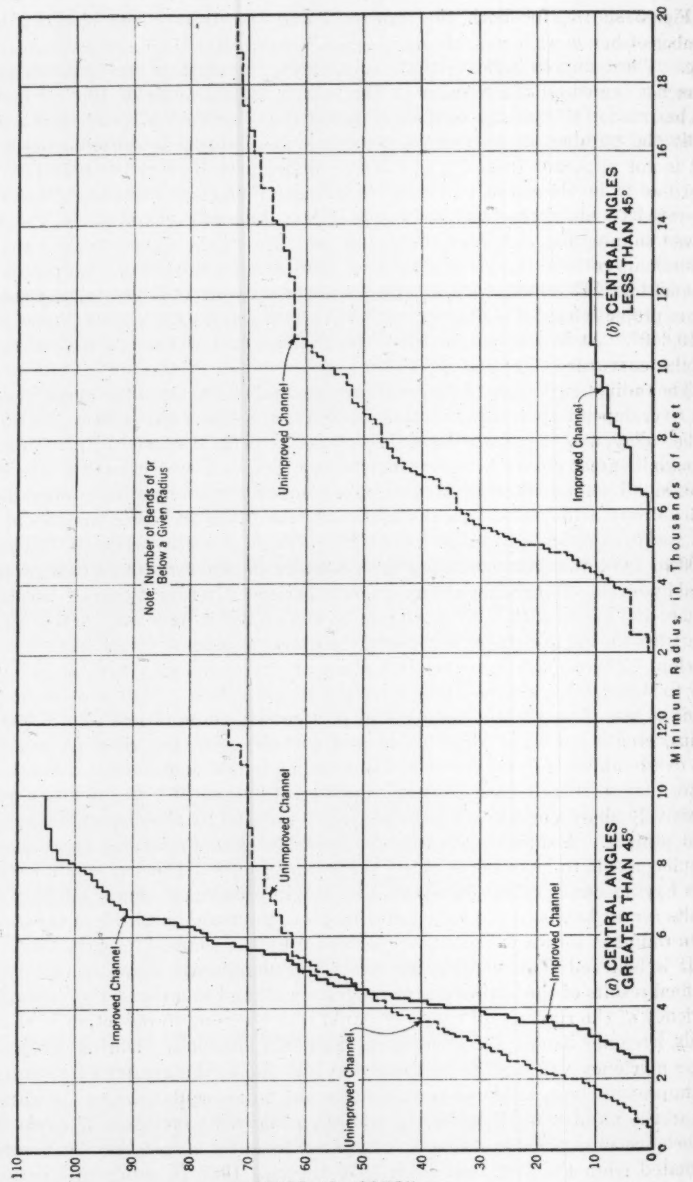

Fig. 6.—Number of River Bends Classified by Their Minimum Radii

the mean flow was about 23,000 cu ft per sec, whereas overbank flow does not start until flows exceed about 75,000 cu ft per sec, and is unimportant except near the crest of unusual floods.

Fort Peck Reservoir.—The regimen of the Missouri River will unquestionably be greatly influenced in some respects by the operation of the Fort Peck Reservoir. This reservoir, with a gross capacity of 19,400,000 acre-ft, controls the entire runoff of the Missouri River above the mouth of the Milk River. Its primary purpose is to regulate the flow of the Missouri River so as to insure required minimum flows during the navigation season at the head of the navigation improvement. Other benefits will result, due to partial flood control of the Missouri River, the production of incidental hydroelectric power, and possible utilization for irrigation.

In general, the effects of this reservoir will be as follows: During all years, flood peaks and overbank stages will be decreased; and during dry years, medium to overbank stages will probably also be reduced. A considerable part of the winter flow will also be stored. During August, September, October, and early November, there will be considerable releases, in practically all years, in order to bring the navigation project up to the desired minimum flow, and during wet years there may be additional excess releases during October in order to draw the reservoir down for flood-control storage. It seems probable that these changes will tend to prevent the aggradation of the channel which has been observed during dry cycles of the past, but in the long run this factor may be balanced by reduction in frequency of high discharges in wetter years. Although detailed studies have not been made for this paper, it is not believed that the operation of this reservoir alone will have an important effect, between Sioux City and Rulo, upon the average ratio between the quantity of sediment brought into the section and its sediment-carrying capacity, for a given slope.

Irrigation Influences.—The extensive past and projected future development of irrigation on a large scale in the Missouri Basin must be a factor tending toward aggradation of the stream bottom. Irrigation projects in the Missouri Basin are ordinarily installed where the water supply is comparatively free from sediment. In this manner a reduced supply of water is available downstream to carry the net sedimentary load of the stream, which is not decreased proportionately. No detailed study has been made as to the extent to which this effect would influence the slope of the Missouri River below Sioux City, but it is probably of minor importance.

Velocity and Slope.—Consideration has been given to approaching the problem of changes in velocity of the Missouri River due to the channel improvements by a comparison of velocities measured by the U. S. Geological Survey in connection with discharge readings over the period of record, from 1929 to the present. However, interpretation would present major difficulties, since the discharge readings were taken at points of the river contracted by bridges to approximately 1,000 ft, which widths have not materially changed since the general reduction in width of the river as a whole. Prior to the improvement work, the contracted sections near the gaging stations would naturally tend to have a slope and mean velocity lower than the average at low stages and higher than the average at high stages of the river. The extent of these departures from the mean would be dependent upon the rate at which the river bed would scour out or silt in following changes in discharge. Data sufficient to determine the slope at these periods are almost entirely lacking. For these reasons, determinations of velocity changes, in order to be applicable to the river as a whole, can be computed by dividing the discharge at the nearest gaging station by the average area of the cross section as obtained by survey.

During 1938 a hydrographic survey and hydraulic study were made of a 25-mile section of river that was almost completely improved. Data were obtained at a discharge of 55,900 cu ft per sec with gages set at approximately 5-mile intervals. The part of the river considered included one long bend, of minimum radius 3,700 ft and central angle 161°; a sharp bend, of minimum radius 3,000 ft and central angle 104°; and three other bends of lesser severity. Results showed considerable variation in roughness coefficient. The mean slope of the entire section was 0.69 ft per mile; the average velocity 4.73 ft per sec; and the mean value of Manning's *n*, 0.0194.

As a check, a similar hydrographic survey and study were made for a 10-mile reach of almost wholly unimproved channel for the same year. This survey was taken at 95,000 cu ft per sec, which is slightly greater than overbank stage in this vicinity, and includes one fairly severe and one very abrupt bend. Only a very few improvement works had been constructed in the part of river under consideration. Values of roughness coefficient obtained varied in about the same range as the values obtained for the improved section of river. The mean slope was 0.91 ft per mile, the average velocity 4.80 ft per sec, and the mean value of Manning's *n*, 0.0197.

Overbank flow at these stages is of minor importance at this point. Any allowance for overbank flow would raise the roughness coefficient and lower the aforementioned average velocity, since these values were computed from the total discharge of the river at this time, as obtained from the nearest gaging station.

[a] A 10-mile section. [b] A 17-mile section.

As of 1938, although construction was underway throughout most of the river between Sioux City and Rulo, there were only five parts of the river in which a single completed channel was established over a sufficient length for comparative slopes to be available. These were, besides the section near Omaha already discussed, sections near Sioux City, and Blair, Nebraska City, and Brownville, Nebr. Recent slopes of these sections are given in Table 1.

It is noted in Table 1, Cols. 3 and 4, that the initial improvement by contraction of five stretches of the river resulted in all cases in a reduction of slope and a resultant slope below the average for the section between Sioux City and Rulo. The reduction was much greater for short sections and particularly the one section with a wide, divided, natural channel. Flood slopes in 1939 were greater on four of the five sections. Low-water slopes in 1940, although still below the general average, were all increased over 1938, coincidentally with the extension of contraction works to other parts of the river.

Values of roughness coefficient are apparently about the same for the improved and the unimproved section of the river. A computation by means of the Manning formula of the velocity that would obtain at each reach at a slope of one foot per mile shows that the unimproved section would have a velocity of 5.04 ft per sec, whereas the improved section would have a velocity of 5.71 ft per sec, although the data for the unimproved channel were taken at a 70% greater discharge. Similar comparisons made between present improved channels and unimproved sections of river in 1932 also show that the mean velocity obtaining, in terms of equal slope and discharge, is considerably higher for the improved river.

SEDIMENT TRANSPORTING CHARACTERISTICS

Data.—In introducing this single problem the writer must acknowledge his indebtedness to comprehensive sediment studies made in this basin for the U. S. Engineer Department by L. G. Straub,[4] M. Am. Soc. C. E. For a general description of the sedimentary characteristics of this basin, as well as for a large amount of basic data, reference must be made to this work. For the section of river under consideration no data were taken between those of the 308 report[2] and a program that was undertaken early in 1939. In the 1939 program, bed-load and suspended sediment samples were taken at Omaha, near the center of the largest section of the improved river above Rulo, and at Yankton, S. Dak., which is many miles above the head of the navigation improvement and represents the unregulated river. The mean width of the river in the vicinity of Omaha is about 725 ft; at Yankton it is about 2,000 ft. The slope at Omaha is 0.71 ft per mile, and at Yankton it is 1.13 ft per mile, both slopes taken during October, 1938, over a stretch of river more than 8 miles long. For the period of sampling the discharge at Yankton was more than nine tenths of the Omaha discharge.

Nature of Problem.—The Missouri River carries a heavy bed load, which has been sampled and analyzed, but which has not been measured as to quantity. In order to establish a future equilibrium, the competence of the improved channel must be sufficient to move the largest particles brought down to it by the unimproved channel above; and, similarly, the capacity of the improved channel must be sufficient to move the total bed load of the unimproved channel. The Missouri River also carries a heavy suspended load, which has been both analyzed and measured. A third condition for equilibrium is that the downstream part of the river must carry the entire suspended load brought to it by the upstream part.

If the river develops transporting characteristics over and above those sufficient to carry its total sediment load in a reach where its banks are stabilized, it will scour deeper, provided that the competence is sufficient to move the material of which the bed is composed.

Suspended Sediment.—Curves (1) to (3), Fig. 7, represent the average of mechanical analyses of suspended sediment at Yankton and Omaha. For 1939 a very close correspondence is shown between the sediment at Yankton and Omaha, with the latter very slightly coarser. In these cases about 20% of the materials shown is very fine sand or coarser, as compared to about 32% as shown on the 1930 curve for Omaha. Fig. 8 shows the rating curves for the relationship between the discharge and the total suspended load at Yankton for 1939, and at Omaha for 1930 and 1939. The wide divergence between observed results at high discharges is noteworthy. In the case of the Missouri River the quantity of finer sediments carried is probably always dependent

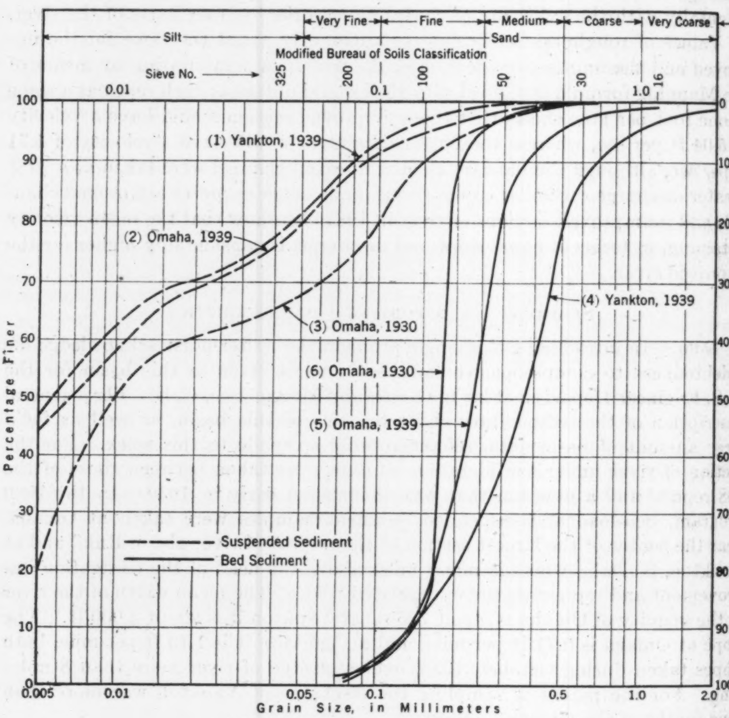

FIG. 7.—AVERAGE OF MECHANICAL ANALYSES

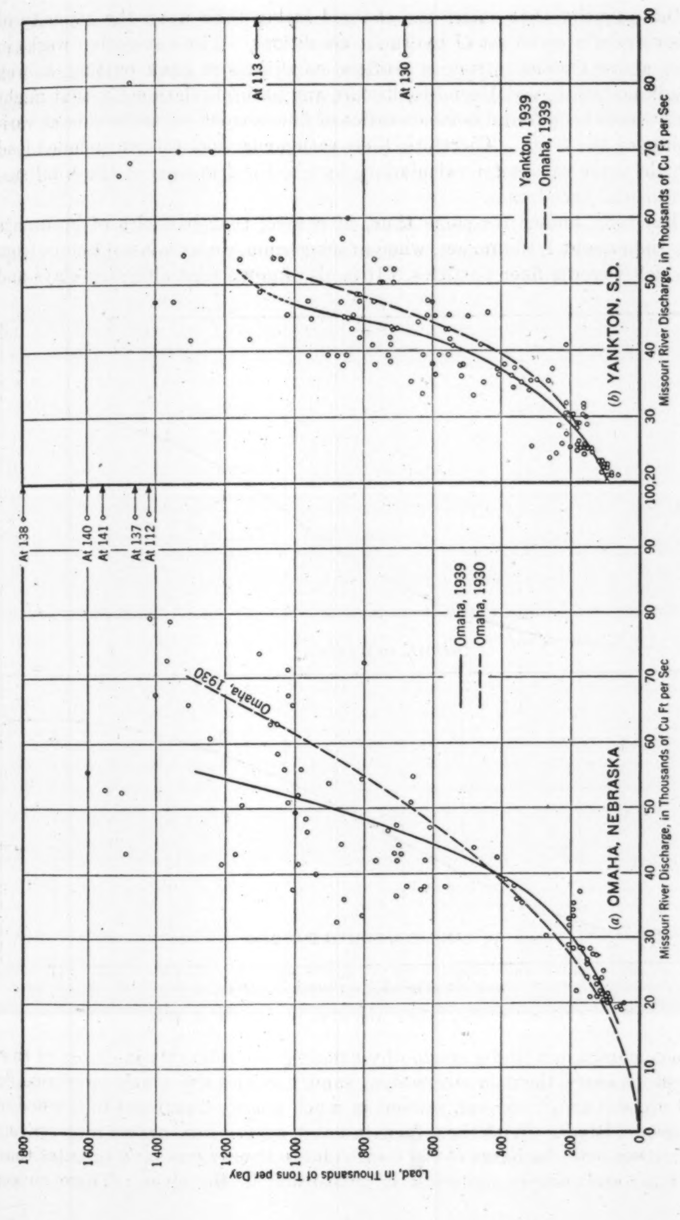

FIG. 8.—RATING CURVES FOR TOTAL SUSPENDED LOAD, 1939

upon the quantity that enters the channel rather than upon the capacity of the river under a given set of hydraulic conditions. The navigation works in progress above Omaha introduce artificial conditions of bank cutting, as well as of sedimentation, which tend to obscure any natural relationship that might otherwise have been found between ratios of finer suspended sediments at various points on the river. Therefore, these rating curves of total suspended load have little value except for calculation, by empirical means, of the total suspended load of the stream.

It has been known for some time, of course, that particles of grain size greater than about 1/16 mm act, when in suspension, under a law different from that which governs finer particles. It is also known that although clays and silts, once compacted, resist erosion by velocities considerably in excess of that sufficient to carry them in suspension, sand particles are much more readily picked up, and are, moreover, present in much greater quantities in the bed of the Missouri River. With these facts in mind, curves were drawn representing the variation with discharge of the total volume of very fine sand (greater than 0.074 mm) and coarser materials in suspension in the river. These curves

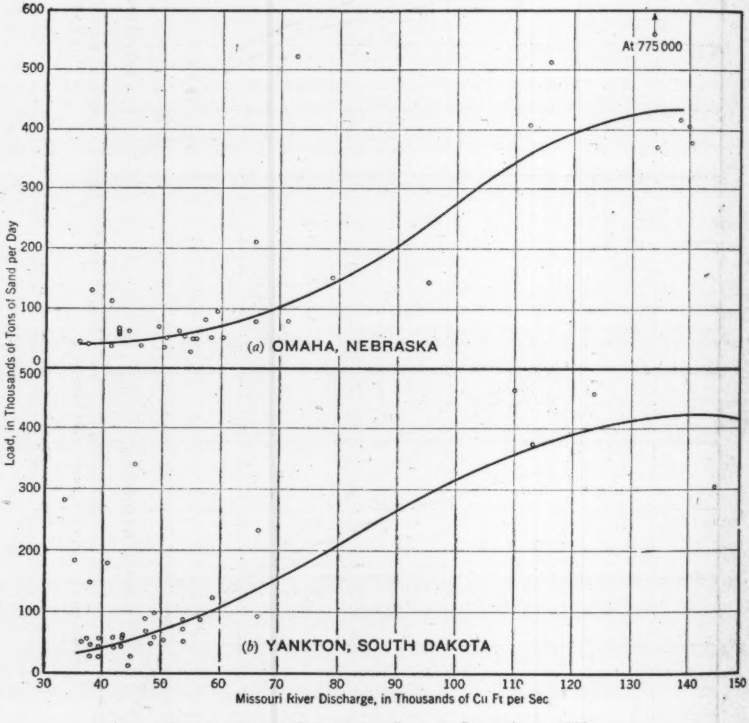

FIG. 9.—RATING CURVES FOR SAND IN SUSPENSION, 1939

are reproduced in Fig. 9. Unfortunately, they show that the suspended sand passing a given point, as well as the total suspended content, varies with parameters other than discharge. Variation in slope and velocity, due to the passage of sand waves on the bottom and to rising or falling stages, are probably among the influences to be considered. However, these local variations should balance when the average is taken of the considerable number of variations, and the mean quantity of suspended sand, rather than total suspended sediment, should be more nearly proportional to the capacity of the stream.

In order to make a more direct comparison of quantities of coarse suspended sediment (material coarser than 0.074 mm) at Omaha and Yankton, respectively, data were taken for a corresponding though non-consecutive period covering 29 days, from April through July, 1939, with allowance for a 2-day time of travel between Yankton and Omaha, in order that the data would be comparable. These are the only corresponding days on which composite samples were taken large enough to contain sufficient quantities of suspended sediment to permit mechanical analyses to be made. Results are given in Table 2.

TABLE 2.—COMPARISON OF DATA, APRIL THROUGH JULY, 1939

No.	Description	Omaha	Yankton	Ratio
1	Average water discharge, in cu ft per sec	70,000	61,800	1.13
2	Average coarse sediment discharge, in tons per day	174,000	134,800	1.29
3	Average total sediment discharge, in tons per day	1,240,000	1,293,000	0.96

Results of Item 3, Table 2, are checked by the fact that for a period of 84 corresponding days (with allowance for travel time) the average total sedimentary discharge was exactly the same for the two stations.

From the foregoing it appears that the Missouri River at Omaha carried a 14% higher concentration of the coarser suspended sediments than it did at Yankton during the same period, the excess having been picked up by scour from the bed or banks or having been brought in by the tributaries. On the other hand, the content of finer sediments was reduced absolutely as well as relatively. Since silts and clays in any appreciable quantity do not settle in the channel of the river, there must have been a large deposit of the finer sediments on bars and behind dike systems between Yankton and Omaha. For lack of an available supply, the river is unable to replace this finer material by scour, although the capacity of the stream for the finer sediments is probably seldom if ever reached at any point, as shown by previous investigations by Professor Straub.

As far as suspended load is concerned, therefore, it appears that the improved section of the river has a tendency, at present, to pick up and carry a net addition to its suspended sediment content from its own bed and banks, even at slopes less than the average now prevailing. The conclusion appears justified that, for a given slope, the improved channel has a greater capacity than the natural river for the transportation of suspended sediment.

Bed-Load Competence.—Fig. 7(*b*) shows graphically the average mechanical analyses of bed sediment samples taken. The results show a predominance of fine and medium sand, with 1939 results for Omaha coarser than in 1930, but not as coarse as those of Yankton in 1939. The Yankton results are probably influenced by its location below the mouth of the Niebrara River, which carries a heavy bed load, and the natural sorting processes present tend to create finer deposits in the lower reaches of a river than are found in the upper sections.

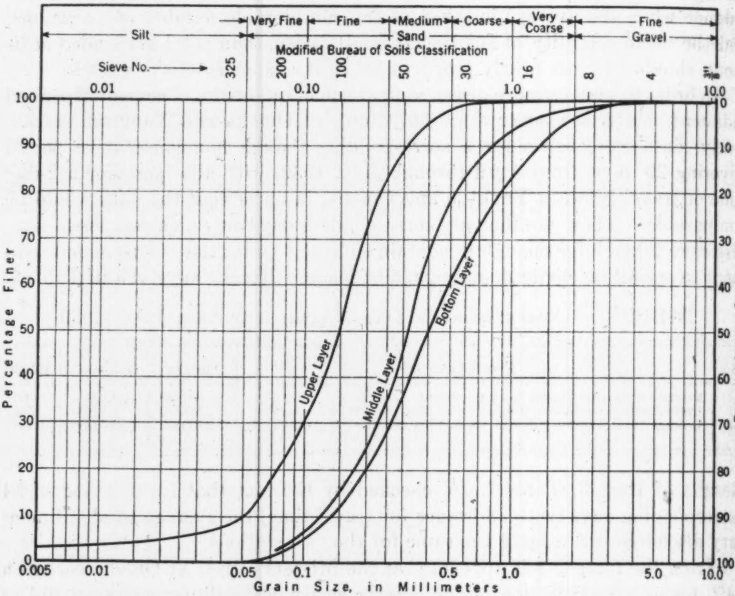

FIG. 10.—SOIL CLASSIFICATION, 10-FT LAYERS OF A BAR ISLAND, GAVINS POINT, YANKTON, S. DAK.

Fig. 10 shows results of analyses of approximately fifty samples taken from a bar island in the river a few miles above Yankton, separated into curves representing successive 10-ft layers from the surface. The lower surface of the bottom layer extends 5-ft below the deepest point of the stream bed at this locality. Results show that nearly all of this sediment is sand, with only 4% of the bottom layer exceeding 2 mm in diameter. Other analyses and field inspections at hundreds of other points throughout the length of the river confirm this general result: There is little gravel in the bed of the Missouri River between Yankton and Rulo except near the mouth of the Platte River.

W. W. Rubey[5] indicates that competence is governed by tractive force formulas rather than the sixth power law when the particles are equal to or finer than a mean diameter of 0.688 mm. Fig. 7 (curves (4), (5), and (6)) and Fig. 10 indicate that Missouri River bed loads may be expected to fall within this range, and therefore should be governed by tractive force formulas.

As has been shown previously, the available slope in the Missouri River in the part being considered is 0.96 ft per mile. It is necessarily assumed that this was sufficient to carry the average bed load with the prevailing discharges prior to the improvement. Roughness coefficients and discharge schedules have been little changed, but mean width is being reduced from 3,650 ft to 725 ft.

---

[5] "The Force Required to Move Particles on a Stream Bed," by W. W. Rubey, *Professional Paper 189-E*, U. S. Geological Survey, 1937.

According to the tractive force criterion, competence equal to that which prevailed previously will be retained if the depth-slope product remains constant. Applying this and other conditions, given previously, to the Manning formula, a slope of 0.24 ft per mile would be sufficient to retain competence unchanged.

A similar result is obtained by applying an equation derived from the Schoklitsch formula[6] by Samuel Shulits, Assoc. M. Am. Soc. C. E., and W. E. Corfitzen, Jun. Am. Soc. C. E.:

$$D_{\max} = 4{,}770 \frac{Q\, S^{4/3}}{B} \qquad (1)$$

in which $D_{\max}$ is the diameter of the largest grain size moved in millimeters; Q is the discharge in cubic feet per second; S is the energy-gradient; and B is the width of the river in feet. According to Eq. 1 a slope of 0.285 ft per mile would be sufficient to maintain competence unchanged.

This result is particularly interesting inasmuch as Messrs. Shulits and Corfitzen were attempting to define not only competence but also, apparently, conditions of a non-silting, non-scouring channel at an actual canal location; and they considered the results from this formula to fall within the approved band of results. To quote, "Hence, the maximum particle-size that can be transported as part of the bed load represents the size of material which would create a non-silting, non-scouring channel." According to this interpretation a slope of 0.285 ft per mile would not only provide competence equal to that existing previously, but would also serve, apparently without further analysis, as the equilibrium slope of the contracted channel.

Messrs. Shulits and Corfitzen also quote a table of critical tractive forces observed by the Nuernberg Kulturamt.[7] For ordinary quartz sand from 0.4 to 1.0 mm in diameter the critical tractive force required was 0.25 to 0.30 kg per sq m. Checking these data by ordinary measurement is complicated by the fact that, when taking a bed-load sample, it is impossible to determine whether or not this sample is in process of movement at the time. Therefore, of the various bed sediment samples for Omaha in 1939 (which were taken at discharges averaging 46,000 cu ft per sec) it is not known whether all samples were taken from moving deposits. However, the assumption will be made that the average sample would move at the average discharge. Substituting the known hydraulic characteristics of the river in the vicinity of Omaha into the Manning formula an average depth of 12.9 ft is obtained for discharges of 46,000 cu ft per sec and the present average slope of 0.71 ft per mile for the nine miles in the vicinity of the gaging station. Substituting, a tractive force of 0.53 kg per sq m is obtained as compared to the 0.25 to 0.30 of the Kulturamt results.

---

[6] "Bed-Load Transportation and the Stable-Channel Problem," by S. Shulits and W. E. Corfitzen, *Transactions*, Am. Geophysical Union, 1937, p. 457.

[7] "Der Wasserbau," by A. Schoklitsch, Julius Springer, Vienna, Vol. 1, 1930, p. 127.

Examining the average mechanical analysis of bed-sediment samples, at Omaha (Fig. 7), only 1% of the sample was found to be coarser than 1.0 mm. It is probable that this small percentage of larger particles was either moved, during the discharges, much higher than the average that occurred during the period considered, or consisted of particles of shape and specific gravity considerably different from those of ordinary sand particles. For the average discharge it is believed that 1.0 mm represents, as nearly as can be estimated, the largest particle that was moving. Moreover, when mean grain diameter is plotted against discharge on the day the sample was taken, there is comparatively little variation. Mean grain diameter increased less than 50% between 20,000 and 140,000 cu ft per sec, and the three coarsest samples were actually taken at fairly low discharges. The only reasonable explanation for these results is that the Missouri River does not now find, in its bed, sediments as coarse as those which it is competent to move at fairly high discharges. This being the case, the criteria of competence cannot define the future equilibrium of the channel except possibly below the mouths of gravel bearing tributaries.

Capacity.—The Schoklitsch bed-load formula is:

$$G = \frac{86.7\, S^{1.5}}{\sqrt{D}} (Q - B\, q_0) \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

in which G is the bed load in pounds per second; and D is the grain-diameter in inches. In this formula the factor $B\, q_0$ represents the discharge at which bed-load movement begins, which has been shown in the Missouri River 308 report to be very small in this case, in proportion to the average discharge. Therefore, since the discharge schedule will have no changes of material effect, changes in the expression $Q - B\, q_0$, as between the improved and unimproved channel, can be dismissed as negligible. Surprizingly enough, there are no other factors in this equation that show any variation under the conditions stated. Therefore, Eq. 2 must involve some inherent assumption as to the relationship between width and slope, or width and discharge, which entirely unfits it for present uses. Since this equation was principally based on flume experiments, its empirical form renders its application to natural streams questionable unless verification can be made on a large scale.

Formulas probably more applicable to the conditions in the Missouri River were developed by Professor Straub[8] for the "308" report. His applicable equation is:

$$G_w = \frac{u\, i^{1.4}\, Q^{3/5}}{c^{1.2}} (Q^{3/5} - Q_0^{3/5}) \dots\dots\dots\dots\dots\dots (3)$$

in which G_w is the quantity of sediment transported along the stream bed in pounds per unit width of channel; Q_0 is the discharge per unit width of channel (for a slope i) at which sediment transportation begins, c is the roughness coefficient in an open-channel formula, corresponding to the Manning expression $\frac{1.486}{n}$, and u is the "sediment characteristic," depending upon the physical characteristics of the sediment carried. For present purposes Q_0 may be neglected, since, although it may be varied somewhat by the contraction of the channel, it was very small (even prior to contraction) in proportion to the average discharge. The quantity of sediment, G, must be assumed to be the same for the improved or unimproved channel, which is also true of C and the sediment characteristic u. Substituting known characteristics, the reduction in width of the channel from 3,650 to 725 ft is found to cause a reduction in the equilibrium slope from 0.96 to 0.76 ft per mile, as an equilibrium condition for a bed load for which the steeper slope would otherwise have been an equilibrium condition. This accords quite closely with the slope of 0.69 ft per mile which is actually in existence in the 25-mile improved stretch in the vicinity of Omaha at the present time, and with slopes on other improved parts of the Missouri River.

---

[8] "Effects of Channel-Contraction Works Upon Regimen of Movable Bed Streams," by L. G. Straub, *Transactions*, Am. Geophysical Union, 1934.

In fairness to Professor Straub it must be noted that his formula was designed for a uniform discharge, whereas the Missouri River discharge is variable; and that he contemplated measurement of widths at low water, whereas the data used are taken for convenience at medium stages. Greater refinements would probably show slightly different results from the foregoing. Investigations such as those summarized in this paper bring to light great deficiencies in basic data as to the principal hydraulic characteristics of major streams. A few more years of study may provide data which will change, materially, the incomplete and short-period records utilized for this paper.

Using all data available, a very approximate estimate could be made as to the time required for a 250-mile stretch of river with an existing slope of 0.96 ft and an equilibrium slope of 0.76 ft to scour its bed by any given amount. This attempt will not be made herein because, although certain parts of the river are practically completed, there are other parts where the channel is only partly formed, and where contracted sections, split channels, and protruding dikes, not yet silted in, form obstructions to flow that interfere with, and delay, the process and would render any estimate in quantitative terms very approximate. However, recent stage discharge relationships show that the process is already under way.

CONCLUSIONS

It is concluded that locally steep slopes are caused by rock protrusions, sharp bends, crossings, tributary influences, and reentrant chutes, besides temporary factors. Long meanders also increase slope at overbank stages. Since the improvement project will reduce the number of crossings, eliminate chutes, and reduce the number of sharp bends, its general shape will tend to allow the river to reach a flatter slope, even though at overbank stages the additional curvature of the improved river is a counteracting influence.

It is concluded that Fort Peck Reservoir will probably not have any important effect on the mean slope of the stream; and that future irrigation development, although tending toward aggradation, will probably be of slight importance.

The improved and unimproved channels have equal roughness coefficients in the reaches examined; and the improved channel has a greater mean velocity relative to the slope, due to its greater hydraulic radius. Improved sections of the river now maintain themselves at less than the present (or the 1930) average slope.

It is concluded that during 1939 the Missouri River in the improved section at Omaha had a greater capacity for suspended sediment than it had on the unimproved section at Yankton, despite a considerably flatter slope.

An analysis of comparative bed-load competence of the improved and unimproved rivers shows that the tractive force criterion, and an equation derived from the Schoklitsch formula by Messrs. Shulits and Corfitzen, both indicate that a future equilibrium slope of less than 0.3 ft per mile would be sufficient to retain competence unchanged in the contracted channel. Since the Missouri River does not now find in its bed sediments as coarse as those which it is competent to carry at high discharges, it is concluded that bed scour of this stream is limited by capacity, and that formulas for competence will not define an equilibrium condition in this case. The Schoklitsch bed-load formula is inapplicable to the change of regimen of the Missouri River.

Applications of Professor Straub's bed-load formula indicate that, if other things remain equal, contraction of the Missouri River should increase its capacity for bed load by 38%, or reduce from 0.96 to 0.76 ft per mile the average slope at which a section could carry an unchanged bed load. Slopes on parts of the river first contracted correspond fairly well with this analysis. In view of the great length of river involved, no appreciable change in mean slope can be expected; but a progressive lowering of the bed of the stream through scour will probably continue for some time.

DISCUSSION

Samuel Shulits,[9] Assoc. M. Am. Soc. C. E. (by letter).—Captain Whipple's paper merits attention as an analytical treatment of a problem in river regulation. Too frequently river engineers opine qualitatively on the behavior of rivers—one reason why the science of river engineering has moved forward so slowly.

The assumption of an average slope as the basis of the improvement of the Missouri River seems untenable. The word "average" implies a time interval that must affect the magnitude of the "average." It is not easy to accept the tenet of an average slope when the author states that the slope had been increasing for several decades prior to the improvement program and that there have not been enough data to predict the future trend. An average slope does not "jibe" with the recognized fact that the eventual Missouri River slope depends primarily on its sediment-carrying characteristics, which can scarcely be related to an average gradient. If the long view is taken, an average has no significance; and if a short range is taken, the application of the average to a specific problem seems precarious. The writer believes that there is no basis for the rule of thumb that a river has an average slope to which it must return regardless of the regulation measures adopted.

Although detailed studies have not been made for the paper, the effects of Fort Peck Reservoir and of irrigation projects are deemed to be of negligible future influence between Sioux City, Iowa, and Rulo, Nebr. The present state of knowledge is inadequate to permit such conclusions. Is it not possible that a very slow progressive degradation may occur below Fort Peck Reservoir due to a desilting of silt-laden flood flows in the reservoir? The Bureau of Reclamation is measuring, very carefully, the morphologic behavior of the Colorado River below Hoover Dam almost all the way to the Mexican border.

Of particular interest is the application to the Missouri River of some of the findings since 1930 in the field of bed-load formulas. Since these formulas are the keystone of the conclusions on the equilibrium slope of the Missouri River, it is incumbent to subject them to a rigorous critique.

The Schoklitsch bed-load formula (Eq. 2) is imputed to be based principally on flume experiments and it is asserted that its empirical form renders its application to natural streams questionable unless verification can be made on a large scale. Then the belief is expressed that the Straub formula (Eq. 3) is more applicable to the conditions in the Missouri River. There is little evidence, if any at all, for these contentions because: First, as far as the writer is aware, the Schoklitsch formula is the only one for which there is any large-scale verification and it has been confirmed for three rivers;[10] second, the Schoklitsch formula has a good rational basis, whereas the Straub formula is the result of substituting the Manning velocity formula into the du Boys bed-load formula, and the latter is predicated on an assumed manner of sand motion known to be untrue;[10] and third, both formulas found their claims and coefficients on flume investigations—the numerous tests of G. K. Gilbert (mainly) in the case of Professor Schoklitsch and the comparative few of F. Schaffernak in the case of Professor Straub. These three facts render untenable the author's assumption that the Straub formula is more representative of Missouri River conditions; besides there is no physical evidence to substantiate the claim for the Straub formula.

---

[9] Hydr. Engr., U. S. Engr. Office, Charleston, S. C.

[10] "The Schoklitsch Bed-Load Formula," by S. Shulits, *Engineering*, June 21 and 28, 1935, pp. 644–646, and 687.

The surmise is incorrect that the Schoklitsch formula contains some inherent assumption of the relation of width to slope or discharge. The formula is based almost entirely on the Gilbert measurements, using the bed load and discharge per unit width of flume, as is the case with all such formulas. The difficulty here, not remedied by any bed-load formula known to the writer, is the fact observed in rivers[11] that movement occurs only over a part of the bed. There is no movement near the sides or banks. The width of the moving strip seems to vary directly with the discharge, but this is not incorporated into the Schoklitsch formula.[12]

The point is made that the Schoklitsch formula does not have more factors to vary for given conditions and yet it is assumed that G, Q, and u in the Straub formula must be the same for the improved or unimproved channel. This leaves the roughness coefficient, $\frac{1.486}{n}$, and the width as the only variables to reflect altered channel conditions. Since the improved and unimproved channels are stated to have equal roughness coefficients, the width remains the only variable factor, and it occurs in the Schoklitsch formula. It may be inferred, therefore, that the Schoklitsch formula is also applicable to the Missouri River problem under discussion. Actually, the magnitude of n, when the bed load is in motion, can be 20% to 35% over its value at the critical discharge of incipient movement,[13] a possibility neglected in this paper.

The computation of the equilibrium slope is based on the valid assumption that the critical discharge is negligible. This changes the Straub formula to:

$$G = \frac{u}{c^{1.2}} S^{1.4} Q^{1.2} \qquad (4)$$

If the Schoklitsch formula is treated in the same way,

$$G = \frac{86.7}{D^{0.5}} S^{1.5} Q \qquad (5)$$

Current knowledge of solids transportation is still too meager to permit a positive decision for 1.4 instead of 1.5 for the exponent of S or 1.2 instead of 1 for the exponent of Q. Consequently little can be said for or against the one equation that cannot be applied to the other—and any choice must be arbitrary to a considerable degree. The situation is similar to the choice exercised in the use of exponential velocity formulas, always a matter of personal familiarity with the formula and its coefficients. With regard to Eqs. 4 and 5, the selection simmers down to whether one prefers to choose a value of u (which is determined by the grain diameter) and estimate c (a roughness coefficient which, for some reason, is made to be $\frac{1.486}{n}$), or to select the effective grain diameter (D) in the Schoklitsch formula.

[12] "Der Geschiebetrieb und die Geschiebefracht," by A. Schoklitsch, *Wasserkraft und Wasserwirtschaft*, No. 4, 1934, p. 37.

[13] "Beitraege zur Frage der Geschwindigkeitsformel und der Rauhigkeitszahlen fuer Stroeme, Kanaele und geschlossene Leitungen," by A. Strickler, *Mitteilungen des Amtes fuer Wasserwirtschaft*, No. 16, Bern, Switzerland, 1923.

The resemblance between the two formulas becomes even greater upon closer analysis of the coefficient u. It can be shown from experimental data that:

$$u = \frac{K}{D^{0.75}} \qquad (6)$$

in which K is a constant, equal to 111,000 if D is expressed in millimeters. Eq. 4 then becomes:

$$G = \frac{K}{c^{1.2} D^{0.75}} S^{1.4} Q^{1.2} \qquad (7)$$

so that there is $D^{0.75}$ to compare with $D^{0.5}$; and the case is just as strong for the one as for the other. Since considerable latitude is possible in practice in the choice of c or n for rivers like the Missouri, close agreement should be possible between Eqs. 5 and 7 by using in the latter a value of the roughness coefficient well within the limits of accuracy of the coefficient. Thus it is not just to condemn the Schoklitsch formula for the Missouri River and to uphold the Straub formula as "probably more applicable."

The writer would be interested to know what value of u was used and how it was obtained in the section, "Capacity"; what c or n was employed; and then how the equilibrium slope of 0.76 ft per mile was computed.

Leo M. Odom,[14] Assoc. M. Am. Soc. C. E. (by letter).—Because of the tremendous expenditures that have been made on the improvement of the Missouri River, it is highly gratifying that the profession has received the benefit of a discussion of the principles upon which the general improvement is based and of the results obtained.

Improvement of the Missouri River for navigation is certainly a task of magnificent proportions. The totals are overwhelmingly immense and the design in practically all of its phases involves forces and actions of Nature, the understanding of which (in spite of all the mathematical gymnastics and lengthy dissertations that an intensely scientific age has produced on the subject) seems almost as remote as it did when General Humphreys commenced his Topographical and Hydrographical Survey in 1850.

In arriving at a solution for river control, as in most of the problems that beset the river engineer, he may utilize any and all of the following approaches: (1) Cut and try; (2) judgment based on observation of similar problems; (3) mathematical formulas; and (4) small-scale models. It seems to the writer that all of the writing in the past few years has been about approaches (3) and (4), and most of the work has been performed by the use of approaches (1) and (2).

---

[14] Chf. Engr., Dept. of Public Works, State of Louisiana, Baton Rouge, La.

The author sets forth the general plan of improvement that has been evolved and gives briefly the methods and procedure by which the general plan is to be accomplished.

It was decided at the beginning of the improvement that, although the river meandered widely in Nature, its average slope was still ample to provide self-cleaning velocities and that the course of improvement for low-water navigation should be restricted, in so far as practicable, to confinement of the low-water flow to a well-defined channel, meanwhile revising the alinement so as to obviate direct attack and crossing bars. These considerations led the Engineer Department to propose changing the alinement of the river to a continuous series of sweeping curves. The adoption of this proposal embarked the federal government on a project which, of its kind, is the largest that man has ever attempted. The determination of the controlling radii and central angles of the curves to be used was undoubtedly done in the broad laboratory of Nature itself. All that remained was to fit in these curves as economically as possible, and the general plan was complete. The writer believes that the method of cut and try, combined with judgment, was used practically exclusively in evolving this plan.

The author presents a good summary of the type of material borne by the stream, both as to bed load and suspended sediment. The writer cannot follow his discussion of the mechanics of bed load and suspended load movement. The suspended load to be found in a cross section is dependent on the turbulence to a much greater extent than on the velocity, and, although the velocity may give a rough index of the turbulence, it does not do so necessarily. Furthermore, the movement of the major percentage of the detritus progresses downstream by "trading" and not as a continuous process.[15] With these two facts in mind, the author's discussion and conclusions in some cases seem vague. The detritus content in any cross section would not necessarily indicate that the total quantity is progressing downstream since it is highly probable that a large part of such detritus is in the process of transverse movement.

The author's comparison of the results obtained by the improvement with the answers obtained by formulas is interesting and enlightening. The writer had never seen the first two formulas before and was, therefore, not disturbed to learn that they will not work. As to the Straub formula, it is rather a disappointment to learn that it will not work on the river from observations of which it was derived.

The author's statement that the Straub formula was designed for uniform discharge only is in disagreement with the derivation of the formula given in the "308" report on the Missouri River. It is stated therein that the slope is assumed to remain constant; variation of depth and discharge is not supposed to affect the accuracy of results. It is not exactly clear what effect the stage of the river at which widths were measured could have on results given by the formula as cited, since the formula is intended to give the quantity of sediment transported per second along the stream bed in pounds per unit width of channel.

---

[15] "Mineral Composition of Sands from Mississippi River Tributaries," by R. Dana Russell and Leo W. Hough, *Proceedings*, Geological Soc. of America, 1937, p. 109.

Two glaring weaknesses that are apparent in most river work today are revealed by this paper. One is the fact that the location and number of continuous observation stations frequently are not suitable for design requirements. Another weakness is in the practice of constructing improvement works without an adequate knowledge of what was occurring in the section of the river prior to the improvements. This practice is indicated in the paper in that the author is forced to compare the action in a 25-mile section of the improved river with a different 10-mile stretch of unimproved river at a different discharge. A comparison such as that is of doubtful value. The only logical way to find out whether improvements are accomplishing the desired end would be to have sufficient data on the improved section taken prior to the improvement to provide a basis for comparison with its condition after improvement. The adoption of a common-sense theory of improvement such as was followed in this case is good practice; but all theories, of whatever origin, bear careful checking in the field. The only way that engineers can be absolutely sure that their improvement works are accomplishing the desired results is to make a detailed "before and after" comparison, on the section of river improved.

The author has examined the value of the formula approach to design of river-control works. It would be very enlightening to have a similar examination of the value of small-scale models, since, undoubtedly, they have been used in connection with the design of works on the Missouri River.

E. W. Lane,[16] M. Am. Soc. C. E. (by letter).—Considering the magnitude of the Missouri River improvement project, very little has been written about it, and hydraulic engineers will be very much indebted to the author for his interesting exposition of the principles underlying it. This improvement probably constitutes the most extensive application of the contraction of streams as a means of deepening them for improving their navigability, a procedure which is one of the oldest in the science of hydraulic engineering. A search, by a hydraulic engineer, of the ancient writings of Egypt, Mesopotamia, and China would probably show earlier writings on the principles involved, but the earliest known to the writer is by Chi-Husn Pan in the latter part of the sixteenth century.[17] Mr. Pan argues at length in favor of confining the Yellow River between embankments and making it deepen its channel by scouring out its bed.

Although the Chinese apparently knew many of the principles of river control before the Europeans, this knowledge has had no influence on the development of the present-day science. So far as is known, the earliest work leading to modern knowledge was that of Guglielmini in the latter part of the seventeenth century. He stated that the greater the quantity of water that a river carries, the less will be its fall, which statement was used as the basic principle of plans for contracting rivers. The subject seems to have been a matter of frequent discussion in Europe before the latter part of the eighteenth century. At this time Paul Frizi and M. Gennete[18] argued in favor of keeping rivers in a single channel rather than having them branch near the mouth, as the single channel would have less fall and cause less flooding.

[16] Prof., Hydr. Engr., State Univ. of Iowa, Iowa City, Iowa.

[17] "Review of River Protection," by Chi-Husn Pan (translation by Hsing and Wong).

In the United States the principles involved were the subject of active discussion in connection with the improvement of the Mississippi River nearly a century ago. At that time it was proposed to deepen the Mississippi River for navigation and flood control by preventing the overflow of the banks at high-water time by means of levees. This discussion developed into one of the greatest of engineering controversies in connection with the improvement of the passes of the Mississippi River by the late James B. Eads, F. Am. Soc. C. E., and the confinement principle of improvement was adopted as the basis of the early work of the Mississippi River Commission. Although successfully applied to the improvement of the mouths of the river, it was not a success when applied, as a means of flood control, to the entire river, and was superseded by the "levees only" principle. The success in one case and failure in the other was largely due to the tremendously greater quantities of material involved in the case of the entire river, and the lack of a quantitative analysis of the problem, for, although data for an exact solution are still unavailable, it is possible to show by a computation of the quantities that would be moved and the time required, using data then available, that its application to the entire river would fail. The difference between the quantitative relations given in the paper and the almost entire lack of discussion in quantitative terms during the early Mississippi controversy show that appreciable progress has been made in the science, but the qualitative nature of the author's conclusions indicates that considerable progress is still necessary before a prediction can be made of the time interval required to bring about the desired results.

It is believed that the author would have clarified somewhat the picture of the results of the contraction works if he had amplified the statement in his "Conclusions" that "In view of the great length of river involved, no appreciable change in mean slope can be expected." In the "Synopsis" one reads the statement that the mean slope of the river will eventually decrease through the operation of the contraction works, and later quantitative relations are given tending to show that the equilibrium slope would be reduced from 0.96 to 0.76 ft per mile, a change of 21%, which is in agreement with the 0.69 ft per mile slope observed in an improved stretch. When these statements are followed in the "Conclusions" of the paper, with no further explanation, by the statement that no appreciable change in mean slope can be expected, it seems probable that some readers of the paper may be confused. If this is the case, perhaps the following discussion will aid in clearing up the picture of what will probably take place.

It appears to the writer that there are two more or less distinct effects of the construction of the contraction works: (1) The change of shape of the channel from a wide shallow one to a narrower and deeper one, and (2) a change of the gradient of the stream as it tends to reach equilibrium under the changed conditions. The first of these will tend to take place relatively rapidly, especially the major part of the total change, but the second will be active for a much longer period, and equilibrium will not be reached for many years even from a practical standpoint, for theoretically equilibrium would never be achieved.

---

[18] "An Investigation of the Transportation of Bed Load by Flowing Water," by F. T. Mavis; thesis presented to the Univ. of Illinois, Urbana, Ill., in 1935, in partial fulfilment of the requirements for the degree of Doctor of Philosophy (see p. 110).

To carry the flow of the river at a width of 725 ft, which formerly flowed over a width of 3,650 ft, without raising the water surface, will require a deepening of the bed. Fig. 11 shows the depths required for various discharges using the slope of 0.96 ft per mile in both cases. The difference in depth at any given discharge that would give the same water surface elevation for these two conditions is indicated by the vertical distance between the two lines. Thus, to obtain, at bankfull elevation, the same discharge in the contracted as in the uncontracted channel (at which stage the unimproved stream discharged about 80,000 cu ft per sec) would require a deepening of the bottom of about 16.5 − 6.3 = 10.2 ft. Under these conditions the area of the channel at bankfull level would be reduced from 23,000 sq ft for the unimproved channel to 12,000 sq ft for the improved channel, a difference of 11,000 sq ft. The area of excavation would be 725 × 10.2 = 7,400 sq ft and the area of fill (3,650 − 725) 6.3 = 18,400 sq ft. The space that would be filled in with sediment under the improved conditions, if it fills to former bank levels, is therefore 67% more than the volume that it is necessary to excavate in the contracted section. Since the competence of the stream is much greater than required to move the largest bed particles, if the size of the bed material does not increase substantially with depth, it is not unreasonable to expect that considerable of the deepening due to contraction will proceed rapidly, as the material excavated at one point along the channel can be deposited outside the contracted section a short distance downstream. However, the river carries great quantities of material in suspension which will deposit in, and rapidly fill up, the parts of the old channel outside the new channel line. As this filling takes place, the deepening of the contracted channel will slow up, and

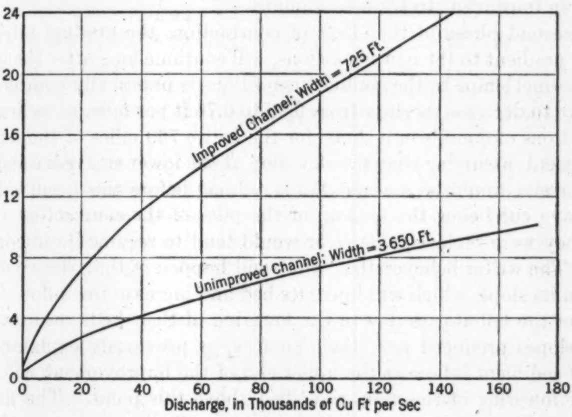

FIG. 11

although the first part of the deepening will probably proceed quite rapidly it may be some time before the final depth is reached.

The deepening of the channel will result in a cutting down of the bottoms of all tributary streams that are not restrained by rock ledges or deposits of coarse material. After the adjustment of channel cross section is substantially completed, at high discharges the water levels in the Missouri River will differ little from those at present; but at lower discharges in the contracted channel they will be considerably lower than in the unimproved conditions, and the bottoms of tributary streams will tend to cut down to lower levels, due to the increased fall that will be caused near their mouths as a result of the lowering of the bed in the main river. This action will bring into the main river an additional load of material that will have to be deposited in the unimproved channel area if the improved channel is to continue to deepen. This action will further slow up the deepening of the bed of the improved channel. There appears to be no way of making a close estimate of the rate at which lowering of the bed of the improved channel can be expected, except by using the experience in improved stretches as a guide.

The second phase of the effect of contraction, the gradual adjustment of the river gradient to the new conditions, will continue long after the adjustment of the channel shape to the confined conditions is practically complete. If the river were to decrease its slope from 0.96 to 0.76 ft per mile, as indicated by the computations of equilibrium slope, for the entire 760 miles of the length of the improvement, assuming that the elevation at the lower end remained the same, the upper end would be lowered 152 ft. Long before this occurred, the river would have cut below the bottom of the piles of the contraction works, and, unless they were replaced, the river would tend to resume its unconfined condition. The writer believes that what will happen is that the river will tend to flatten its slope, which will lower its bed and increase the inflow of sediment load from the tributaries due to the lowering of their beds resulting from the steeper slopes produced near their mouths, as previously explained. An increase of sediment inflow at the upper end of the improvement will also result from the lowering of the main river bed above this point. The flattening of the grade due to confinement will continue until the sediment inflow will increase and become equal to the capacity of the stream to transport material in its confined condition, and when this condition is reached no further decrease in slope will be observed. It is the writer's belief that this condition of substantial equilibrium will occur before much lowering of the stream bed due to changed slope has occurred, although it is probable that the lowering at the upper end will be sufficient to be easily detectable in the stage-discharge relations at that point. It is doubtful if the mean slope of the river will be changed more than 2% or 3% for many years to come, which substantially agrees with the author's statement that the change will not be appreciable.

If this be true, what then is the "equilibrium slope" computed by the author? This is the slope at which the confined river would carry the same load of material as the unconfined river carried at its natural slope. Soon after the works are constructed, however, the load to be carried will be increased and a slope greater than the computed equilibrium slope will be required.

The author states that the Schoklitsch formula could not be used to compute the equilibrium slope, which is true for the form given in Eq. 2. An examination of the paper, however, shows that this form was obtained by Schoklitsch by multiplying the load and discharge per unit width by the width, thus obtaining the equation in terms of the total load and total discharge. It can be expressed as well in terms of the load and discharge per unit width, which gives

$$G_1 = \frac{86.7\, S^{1.5}}{\sqrt{D}} (Q_1 - q_0) \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which G_1 and Q_1 are the sediment discharge per unit width and water discharge per unit width, respectively. Using this equation with the formula for q_0 given by Schoklitsch, it is possible to compute the author's equilibrium slope by this formula.

In discussing the formula developed by Professor Straub, the author states that the quantity of sediment must be assumed to be the same for the improved or unimproved channel. As previously shown, the quantities of sediment would not be the same in these two cases, and hence the formula will not give the slope that will actually be obtained in the river; it will give a flatter slope. The author also states that the sediment characteristics must be the same in the contracted as in the uncontracted stream. If the size of material increases with depth as shown in the analysis of samples given in Fig. 9, this condition also is not fullfilled, since coarser material would be encountered as the channel scoured deeper, and a steeper slope than computed would result from this cause.

There is considerable reason to question, however, whether accurate results can be obtained in computing the effect of contraction works on the Missouri River by considering only the bed load. The suspended load of sand carried by this river is very large, as shown by Fig. 9. A comparison of this observed sand load at Omaha and Yankton with the bed loads computed according to the Schoklitsch formula for a wide range of discharges, as shown in Tables 3 and 4, indicates that the bed load is probably never as much as 10% of the suspended load of sand in the Missouri River. Of course, it is a much smaller part of the total load, but the sand particles settle rapidly and therefore have a much larger effect on stream formation than the silt and clay sizes. The suspended sand load no doubt consists, on the average, of finer material than the bed load, and some sizes carried by bed load are moved in suspension in negligible quantities, if at all. In Tables 3 and 4 are also given the computed bed loads for various size ranges and the quantities carried in suspension of these same size ranges computed by the method developed by A. A. Kalinske,[19] Assoc. M. Am. Soc. C. E., and the writer. This comparison shows that the suspended loads are greater than the bed loads for all sizes less than about 0.3 mm at Omaha and 0.4 mm at Yankton, and for high discharges, where the most active bed formation exists, for all sizes less than about 0.6 mm at Omaha and 0.5 mm at Yankton. In order to indicate the reliability of the relation used in computing the suspended load, a comparison is also given between the computed total load of sand and the observed load, as shown in Fig. 9. This comparison shows a reasonably close agreement between computed and observed suspended sand loads at Omaha, and somewhat less agreement at

[19] "The Relation of Suspended to Bed Material in Rivers," by E. W. Lane and A. A. Kalinske, *Transactions*, Am. Geophysical Union, 1939, Pt. IV, p. 637; also "Engineering Calculations of Suspended Sediment," *ibid.*, 1941.

Yankton, but amply close to indicate a great preponderance of suspended over bed load. In view of the data shown in Table 3, it does not seem unreasonable to believe that in the Missouri River the suspended load may be as potent as the bed load in the channel-forming process.

There seems to be little doubt that the confinement of the Missouri River will cause an increased flow of heavy sediment in it, and that this increased flow will be carried out into the Mississippi River. What will be the effect of thus adding to the load of that stream? Fortunately, the improvements previously built in the middle Mississippi River have been causing, over a long period, a lowering of the bed of this stream up to Chain of Rocks, a rock ledge across the river just below the mouth of the Missouri River. The extent of this lowering has become such that the water depths over the rock ledge have been greatly decreased and a by-pass canal with locks, or a movable dam with locks, is badly needed. The increase of the sediment load from the Missouri River, therefore, will tend to offset this lowering. Whether or not it will be sufficient to reverse the trend and cause a raising of the water levels downstream is a question; it is possible but unlikely. An increase in deposit, however, must occur at some point below the mouth of the Missouri River. Such effects are usually not considered in making river improvements, and their results usually do not become apparent for many years. Sometimes they require expensive corrective measures, as shown by the proposed improvements at the Chain of Rocks, previously cited.

ELLIOTT J. DENT,[20] M. AM. SOC. C. E. (by letter).—From Sioux City to Rulo the proposed channel will have a length of 245.6 miles, and in 1938 the total fall was 236 ft, or an average of 0.96 ft per mile. In his closing paragraph the author states that the improved channel will be able to carry 38% more bed load than the natural channel, or that it could carry the present bed load with a slope of only 0.76 ft per mile which corresponds to a drop of 186.5 ft in the reach under discussion.

If this section of the Missouri River is contracted and otherwise improved so as to increase its bed-load carrying capacity, it is logical to expect erosion at the upper end of the reach until a capacity load has been picked up. This increased bed load should then be carried through the remainder of the section and dumped upon the next lower reach at Rulo. To increase the bed load of the river channels materially, from Rulo to the Gulf of Mexico, is a matter that deserves very serious consideration.

WILLIAM WHIPPLE, JR.,[21] ASSOC. M. AM. SOC. C. E.—The interest shown by those who contributed discussions is much appreciated. Mr. Odom is entirely correct in assuming that the Missouri River control works were designed largely by "cut and try," combined with judgment, and that even now there is a considerable lack of suitable observation stations along the Missouri River (as well as most other rivers). However, practice in this respect has greatly improved; and long-range engineering investigations of the Missouri River are now as thorough as available funds will permit.

---

[20] Col., U. S. Army (*Retired*), Cons. Engr., Washington, D. C.

[21] Major, Corps of Engrs., U. S. Army, Fort Belvoir, Va.

Mr. Odom's point concerning the applicability of the Straub formula to conditions of non-uniform discharge depends upon the rate of change of discharge. Variations in discharge on the Missouri River above Rulo are usually irregular enough to be accompanied by slope changes. Otherwise the formula is applicable.

Professor Lane is to be thanked for his clear explanation of the writer's rather abrupt conclusion that no appreciable change in mean slope for the river as a whole can be expected. He shows that there are difficulties in predicting the time required for the river to scour down to a given slope, by reason of increased sediment inflow from the tributaries, as the main stream lowers its bed. Another reason for caution in this respect lies in the hydrologic irregularity of the Missouri River system. In this basin, sediment conditions differ so widely from year to year that naturally occurring changes may affect the result of artificial works over a period of several years.

Professor Lane questions the assumption made by the writer that the quantity of sediment and the sediment characteristics of the river should be considered as unchanged by the contraction works. This assumption would be unjustified when applied to the river as a whole; but it is a close approximation when applied to the short stretches first contracted. As shown by Table 1, all contracted sections initially assume low slopes, thus verifying the formula applied and the assumptions made. The reach near Omaha had a flat slope before the improvement; but this section was already narrow. The increase in all of these slopes by 1940 was due to the contraction of other portions of the river, with a consequent increase in quantity of sediment. If the quantity of sediment and sediment characteristics of the river as a whole did remain unchanged, the entire river someday would inevitably assume its reduced slope within a deep, canyon-like valley. Such an eventuality is certainly not foreseen by this writer. However, the presence of rock ledges all the way across the channel at some points does raise the possibility that the river may erode a deep channel below one of the ledges, unhindered by increased channel scour from above that point.

The writer agrees with Colonel Dent that it is a serious matter to increase the bed load which must be carried from Rulo to the Gulf of Mexico. However, these channels have been improved concurrently with the Missouri River above Rulo, and should be able to handle the increase.

Mr. Shulits centers his attention on the application of bed-load formulas involving capacity to the change in regimen of the Missouri River brought about by the contraction works. Specifically he objects to the conclusion of the writer that the Straub formula is "probably more applicable" than the Schoklitsch formula to this particular problem. He states that there is no physical evidence to substantiate the Straub formula, and that the Schoklitsch formula "has been confirmed for three rivers," has a good rational basis, and is essentially the same as the Straub formula except for the exponents of two variables.

It is true that the Schoklitsch formula has been applied to three rivers; but such confirmation as was given in the reference cited was partial and approximate. Moreover, the three rivers to which it was applied are the

Danube at Vienna, the Inn, and the Tiroler Ache (all in Austria), which are not similar to the Missouri; and contraction of channel width was not a factor covered by those investigations.

Mr. Shulits demonstrates that the Straub and Schoklitsch formulas can be reduced to forms which are generally similar, and draws the conclusion that the Schoklitsch formula must also be applicable to the problem. However, he did not state any results obtained by applying this formula. In a strict sense, neither formula should be used in the form in which he gives it. The result of channel contraction, as Professor Lane states, must be computed in terms of the unit width of the channel and not of the channel as a whole. However, these equations can be considered to apply to unit widths of a wide channel. If such a channel is contracted, the water discharge per unit width must increase. According to the Straub formula (Eq. 4), the bed-load discharge would increase more than proportionately to the water discharge; but according to the Schoklitsch formula (Eq. 5) the proportion would remain the same. Therefore, considering the total water discharge, the Schoklitsch formula (Eq. 5) would lead to the conclusion that contraction of the channel could not increase the scouring power of a stream or reduce its equilibrium slope in the contracted portions. This conclusion is in violation of the observed facts; and it is for this reason that the Schoklitsch formula was rejected for the purpose. The Straub formula, on the other hand, is well substantiated by the facts.

Mr. Shulits inquires regarding the method of computing the equilibrium slope of 0.76 ft per mile, particularly the values of u and c or n used. In this instance it was not necessary to substitute numerical values for either coefficient, since it had previously been shown that they are unaffected by changes in channel width. Since it is very small in proportion to the average discharge, Q_0 is omitted. This reduces Eq. 3 to:

$$G_w = K\, i^{1.4}\, Q^{1.2} \qquad (9)$$

for bed-load discharge in a unit width of channel. Let W be the channel width; and conditions prior to and after contraction may be denoted by subscripts 1 and 2, respectively. If the slope reduces after contraction so as to carry the same bed load as before, and the water discharge schedule remains unchanged,

$$G_{w1}\, W_1 = G_{w2}\, W_2 \qquad (10)$$

and

$$Q_1\, W_1 = Q_2\, W_2 \qquad (11)$$

Substituting:

$$i^{1.4}{}_2 = \left(\frac{W_2}{W_1}\right)^{0.2} i^{1.4}{}_1 \qquad (12)$$

Substituting 3,650 for W_1, 725 for W_2, and 0.96 for i_1, $i_2 = 0.76$ ft per mile, the new equilibrium slope for the given conditions.

On the subject of average slope, Mr. Shulits has apparently misunderstood the writer. The view, which he condemns, that the river has an average slope to which it must return, regardless of regulation measures adopted, will not be found in this paper. The writer stated that it was assumed in planning the improvement of the Missouri River that its average slope represented approximately a state of equilibrium under conditions then prevailing; and reasons were given for the assumption. As a matter of fact, at the time this improvement was planned, the river was about to reverse its established trend and revert to an aggradation of the channel similar to conditions observed approximately forty years before. An assumption that the existing trend would continue would have been more in error than the actual decision to base plans upon existing conditions. Perhaps the application of this conclusion to a specific problem was precarious, as Mr. Shulits states, but unless a reliable method can be developed to foretell for a decade or more in advance the sedimentary characteristics of a river valley, empirical judgments, however "untenable" theoretically, will continue to be relied upon.

Mr. Shulits points out that a slow degradation of the river bed may tend to occur below Fort Peck Reservoir, due to a desilting of the silt-laden flood flows in the reservoir. There will also be other effects, such as the reduction of the dangerous ice-jam floods on the Missouri River in North Dakota. Data for the solution of the entire problem of the effects of this reservoir have been gathered for about six years, and necessary studies are being made.

However, the Missouri River above Fort Peck carries comparatively little sediment; and Fig. 1 shows the many hundreds of miles of sediment-bearing tributaries that enter between that point and the head of navigation at Sioux City. Long before a given flow reaches the contracted section, any deficiency in the heavier sediments, due to Fort Peck storage, will have been picked up through erosion of banks or bed. Deficiencies in lighter sediments are not an important influence, since these sediments cannot deposit in appreciable quantities in the bed of the contracted channel. It is for these reasons that it is tentatively concluded that Fort Peck Reservoir operation will probably not have an important bearing on the future slope of the Missouri River within the limits considered in this paper. Any influence that does occur will probably be due to alternations in the discharge schedule by Fort Peck storage and not to retention of sediment in the reservoir.

RIGID FRAMES WITHOUT DIAGONALS (THE VIERENDEEL TRUSS)

BY LOUIS BAES,[1] ESQ.

WITH DISCUSSION BY MESSRS. JAROSLAV J. POLIVKA, W. A. MILLER, A. A. EREMIN, YVES NUBAR, AND LÉON G. RUCQUOI.

SYNOPSIS

Attention is called herein to a simple method for the design of Vierendeel trusses with chords of equal moment of inertia, the loads being applied only at the joints. The method is based on the fact that, for these trusses, a point of contraflexure exists in each vertical and that, according to theory checked by photoelasticity, this point is at the midheight of the vertical.

INTRODUCTION

Until recently, the Vierendeel truss has been adapted mostly to designs of highway bridges, railway bridges, steel framed towers, and the structural steel frames of buildings. There is now a tendency to extend this range to the design of cranes, locomotives, steel passenger cars, etc. This type of truss also has possibilities in the design of reinforced concrete. Among the examples of its use in the United States may be cited a group of eight steel bridges, all of the Vierendeel type, constructed in 1936 in Los Angeles, Calif. Since designers in the United States are showing more and more interest in this type, the time seems favorable to open the subject for technical discussion.[2]

HISTORICAL

The Vierendeel Truss Before 1914.—The concept of the simple rigid truss without diagonals (variously termed the "ladder" truss, or the "arcade" truss) is due to Prof. Arthur Vierendeel. In 1893, he adopted this type for the steel steeple of the church of Dadizeele, in Flanders, Belgium. In Tervueren, near Brussels, Belgium, on the occasion of the International Exhibition of Brussels in 1897, Professor Vierendeel designed a riveted steel test bridge, 103 ft long, having two main girders of uniform depth divided into nine panels without

---

NOTE.—Published in January, 1941, *Proceedings*.

[1] Prof. of Stability, Univ. of Brussels, Brussels, Belgium.

[2] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 869.

diagonals. The verticals were joined to the chords by large curved gussets. The angles that were used as the outer flanges of the vertical members were bent, as shown in Fig. 1, to become the inner flanges of the chord members. When it was subjected to load tests,[3] rupture occurred in the panels near the very end of the bridge. Even during this early period, Professor Vierendeel was actively promoting the general acceptance of this type of truss.[4,5]

The introduction of this type of truss without diagonals was such a distinct departure from the accepted practice of the time that it aroused considerable controversy in Belgium. Practically all engineers were radically opposed to the system, some on general principles, and others for reasons of economy or efficacy.

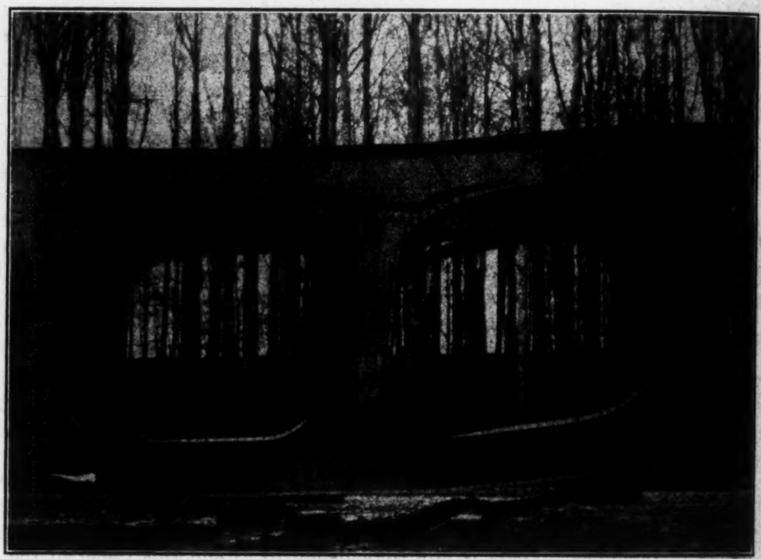

FIG. 1.—END PANELS OF EXPERIMENTAL VIERENDEEL BRIDGE TESTED TO FAILURE AT TERVUEREN (BELGIUM) IN 1897

It is true that, architecturally, these early trusses, for the most part with parallel top and bottom chords, were not attractive. Furthermore, it seems that it might be difficult to rivet a large curved gusset plate at the joint.

Except for the experimental bridge at Tervueren, the first steel highway bridge of this type was built in 1902 at Avelghem, on the Schelde River, with a span of 138 ft. The first steel single-track railway bridge of this type was built, over the Lys River, at Grammene, Belgium, in 1923. The span length was 185 ft and the structure was subjected to systematic load tests recorded in 1925.[6] The first reinforced concrete footbridge was constructed in La Louvière in 1911 with a span of 184 ft. The upper chord was arched and intersected the lower chord at the end of the span.

[5] "Les ponts architecturaux en métal," by A. Vierendeel, *Annales des Travaux Publics de Belgique*, October, 1896.

Prior to 1914, six steel highway bridges were constructed in Belgium. One drawbridge had been designed for Bruges, but was not constructed until 1920. Each of these steel structures had riveted connections. In the first type (the Tervueren Bridge) many of the members had to be cambered; that is, as previously stated, the flanges of the verticals were bent so as to serve as the inner flanges of the chords. No other bridge of this exact type was ever built in Belgium. In subsequent designs, Professor Vierendeel introduced an important simplification permitting a more rational solution; that is, he made the chords continuous throughout. In general, the verticals were made of constant cross section, the flanges being extended up against the chord flanges, the joints being stiffened by angles or by large gusset plates. In other cases, the verticals were made gradually deeper toward the chords, thus forming the large connecting gussets at the joints.

Development Since 1920.—From 1920 to 1939, and more especially from 1928, there has been a marked increase in the number of Vierendeel trusses built in Belgium and in the Belgian Congo. For example, there are about twenty such structures in the Congo, among which may be cited Bukama Bridge with four 202-ft spans. Belgium has more than seventy Vierendeel bridges.

These structures differed, however, from the unattractive types created before 1914, and, following the concept of the bowstring truss with tie rods, most of the Vierendeel bridges built after 1920 were designed with curved top chords (second-degree parabolas) with the height of the end verticals theoretically reduced to zero.

Sixty such highway bridges were built in Belgium between 1928 and 1937. In the list are included two drawbridges and six steel railway bridges, with a few examples of reinforced concrete structures. Examples are shown in Figs. 2, 3, and 4.

Characteristics of the Vierendeel Truss Designed for Bridges

From experience with Vierendeel bridges in Belgium and in the Belgian Congo, the writer has noted the following characteristics favorable to the adoption of the Vierendeel truss with the curved upper chord:

(1) When they are suitably planned and skilfully designed (especially the gusset plates connecting the verticals to the chord members, and the shape of the ends), this truss may be made very attractive architecturally (Figs. 2 and 3).

(2) Under dead load this truss does not react as a Vierendeel truss, but as an ordinary bowstring arch. Consequently, under dead load, the various members are bent very little, if any, and are only slightly stressed.

(3) It is only under moving live loads that the structure really acts as a Vierendeel truss. The maximum bending moment in this truss will be found to be less than in the tied arch.

FIG. 3.—THE DUDZEELE BRIDGE, BUILT IN 1935; SPAN, 104 FT

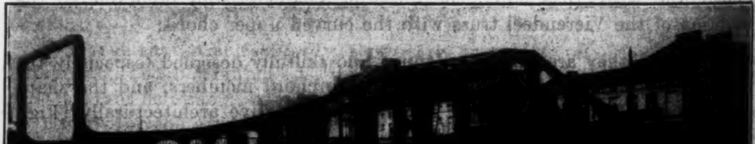

FIG. 4.—DRAWBRIDGE OF MUIDE (GHENT, BELGIUM), BUILT IN 1933; CHANNEL SPAN, 68 FT; AND COUNTERWEIGHT SPAN, 43 FT 6 IN.

(4) Analyzed from the viewpoint of items (1) to (3), the curved Vierendeel truss will often be found more economical than the ordinary tied arch.

(5) Compared with the conventional steel tied arch, the Vierendeel truss inherently has greater stiffness which is a valuable characteristic especially in railroad bridges constructed for heavy and fast traffic.

(6) It is logical and desirable to make both chords continuous. The verticals are simply attached to the chords by means of large connecting plates.

(7) It is logical in principle to design the upper chord with the same section as the lower chord, provided the floor beams are attached only at panel points. Furthermore, it is convenient, in general, to design all the verticals with the same cross-sectional area. These conditions will help to simplify problems of design as well as construction.

(8) As compared with the Vierendeel truss having a curved upper chord, the parallel-chord type is seldom attractive in appearance. The latter should be adopted only in cases where the uniform height is required by the conditions of the design. Furthermore, the stress distribution in the parallel-chord type is much less favorable than in the arch type, particularly in the end panels where the shearing forces are extremely high. Where the parallel chord is necessary, this condition at the end panels can be met by spacing the vertical members closer together near the ends of the truss, as suggested by J. D. Gedo,[7] M. Am. Soc. C. E. The designer, however, might encounter difficulties at least in applying this principle to bridge structures.

(9) With the assistance of arc welding performed with care and skill, the Vierendeel truss becomes a sturdy structure with simple and sober lines, permitting easy maintenance and offering little encouragement to corrosion.

PRINCIPLES OF DESIGN FOR TRUSSES WITHOUT DIAGONALS

Undoubtedly, the greatest obstacle to the general acceptance of the truss without diagonals has been (and still is) its reputation for including certain design assumptions and for being difficult to design.

In the present state, however, the design of trusses without diagonals, having two chords of equal reduced moment of inertia, $I \cos \alpha$, and receiving the loads only at the joints, is as easy as the design of any other type of truss.

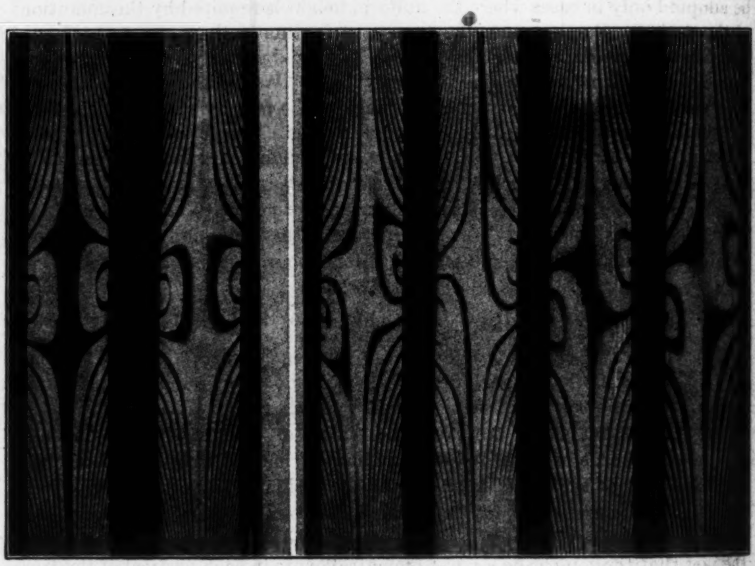
Point of Contraflexure in the Verticals.—From the very beginning of his studies, Professor Vierendeel has stated that the design was predicated upon the fact that there must be a point of contraflexure in each vertical of the truss. When the upper and the lower chords are parallel and have the same moment of inertia, Professor Vierendeel assumed this point to be at the midheight, regardless of the loading, with the assumption that the loads were applied only at the joints. For two chords that are not identical he assumed that the bending moment taken by them was proportioned in the ratio of their moments of inertia, at the sections under consideration. For the tied arch type of truss, he sometimes assumed (to simplify the design) that the points of contraflexure were at the top of the verticals.

---

[7] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 933.

Professor Vierendeel and later writers[8] have attempted to demonstrate that when the parallel upper and lower chords are not of equal cross sections, the point of contraflexure in the verticals occurs in the ratio, $\frac{h_u}{h_l} = \frac{I_u}{I_l}$, in which I_u and I_l are the moments of inertia of the upper and the lower chords, respectively, and the height, h, between the chord axes, is divided, by the point of contraflexure, into an upper section, h_u, and a lower section, h_l. This assumption has been disproved, but it continues to mislead many designers. It is important to emphasize this fact because advocates of this theory claim to have checked it and, thereafter, apply it erroneously but confidently. Other writers have claimed that $\frac{h_u}{h_l} = \sqrt{\frac{I_u}{I_l}}$, a relation which is likewise incorrect.[9]

Still other writers, including Professor Vierendeel himself, have tried to locate the points of contraflexure in the chord members; and they advance systems of design based on this principle.[10] It seems clear now, however, that the points of contraflexure that may occur in the chord members are not fixed points. Their location is variable and depends on loading conditions. Moreover, in the arch type of upper chords, there may be no points of contraflexure



(a) $\frac{N}{T} = 0.3$ (b) $\frac{N}{T} = 2.0$

FIG. 5.—PHOTOELASTIC VIEWS SHOWING STRESS PATTERNS IN THE REGION OF THE POINT OF CONTRAFLEXURE OF A STRAIGHT SPECIMEN SUBJECT TO PLANE BENDING AND AXIAL LOAD

in the chord. Consequently, it is impossible to establish generalized reliable methods of design based on locating points of contraflexure in the chord members. It would be necessary to establish a separate design system for each condition of loading or to obtain a rough approximation.

The controversy has been greatly aided by the introduction of photoelasticity as a laboratory method of analyzing structures. By this means, checked by analytical computations (which agree remarkably well), it has been found that in monochromatic light the lines of extinction in the vicinity of the points of contraflexure are quite characteristic.

Fig. 5 shows two photoelastic stress patterns in the region of a point of contraflexure in a straight specimen subjected to plane bending combined with axial stress. The ratios are $\frac{N}{T} = 0.3$ and 2.0, respectively, in which N = the axial force and T = the shearing force. This photoelastic test was made with monochromatic light. The black curves are extinction lines, or curves of equal

FIG. 6.—GRAPHICAL REPRESENTATION OF THE STRESS PATTERNS IN FIG. 5 AS PLOTTED FROM CORRESPONDING THEORETICAL FORMULAS

tangential maximum stress. Their number depends upon the intensity of the loads applied.

The equations of these curves have been completely derived, and are represented[11] graphically in Fig. 6 for the two cases shown in Fig. 5. It will be noticed how closely these curves check with the experimental photographs.

An extensive program of experiments, covering a range of cases beyond all possible practical requirements, has enabled the writer to confirm the following expression for fixing very approximately the position of the points of contraflexure in vertical members when they all have the same cross section and all panels have the same length:

$$\frac{h_u}{h_l} = \frac{\frac{l}{h} \times \frac{I_v}{I_l} + C}{\frac{l}{h} \times \frac{I_v}{I_u} + C} \quad \text{.......................} (1)$$

in which l = length of panel; I_v = moment of inertia of the vertical; and C is a constant equal to 2.5 in the end verticals and 6.0 in all intermediate verticals. For the case of non-parallel chords I_u and I_l must be replaced by

$$I_u' = I_u \cos \alpha_u \text{......................} (2a)$$

and

$$I_l' = I_l \cos \alpha_l \text{......................} (2b)$$

in which I_u and I_l = the moment of inertia of the non-parallel upper and lower chords, respectively; and α_u and α_l = the corresponding angles between the chords and the horizontal. These expressions—$I \cos \alpha$—are called the reduced moments of inertia of the members. In both diagrams F is the resultant external force, the components being N along axis x and T along axis z.

Eq. 1 was first presented by P. Thomas in 1924,[12] and later verified as being practically accurate by the writer.[11] In most cases encountered in practice, the ratio, $\frac{h_u}{h_l}$, is so nearly constant for both end verticals and intermediate verticals that $C = 6.0$ may be used for all cases. In other words, today, it has been adequately established that for a given value of the ratio, $\frac{I_l}{I_u}$ or $\frac{I_l'}{I_u'}$, the positions of the points of contraflexure in vertical members of a Vierendeel truss depend on the quantities, $\frac{l}{h} \times \frac{I_v}{I_u}$ or $\frac{l}{h} \times \frac{I_v'}{I_u'}$. When the chord members have the same reduced moment of inertia $I_u' = I_l'$, Eq. 1 indicates that the points of contraflexure are always at the midheight of the verticals. The points move upward if: (*a*) The ratio $\frac{I_l}{I_u}$ or $\frac{I_l'}{I_u'}$ increases; (*b*) the verticals become stiffer (that is, if $\frac{I_v}{I_u}$ increases); and (*c*) the ratio $\frac{l}{h}$ increases.

Baes, *L'Ossature Métallique*, October, 1936, Brussels; also, "Étude de la région voisine des points d'inflexion d'une pièce droite prismatique sollicitée par flexion plane composée, avec effort tranchant," by L. Blanjean et F. Temmerman, Prize Paper, *Bulletin de la Société Royale Belge des Ingénieurs et des Industriels*, Brussels, 1937.

[12] "Le calcul des poutres Vierendeel," by P. Thomas, *Revue Universelle des Mines*, Liége, Belgium, November 15, 1924; see, also, issues of August 1, 1926, and November 15, 1926.

Although, theoretically, the position of the point of contraflexure depends on the condition of loading for all ordinary cases, it is practically independent of it if the loads are applied only at the panel points. Moreover, it is only for higher values of the quantity, $\frac{l}{h} \times \frac{I_v'}{I_u'}$, that the points of contraflexure are at an appreciable distance from the center. For all ordinary cases, furthermore, the points of contraflexure in verticals of a Vierendeel truss, carrying no loads except those at the panel points, are at midheight, or very nearly so. The foregoing questions, which have been subjects of discussion since before 1900, have now been solved by analytical methods checked by photoelasticity.

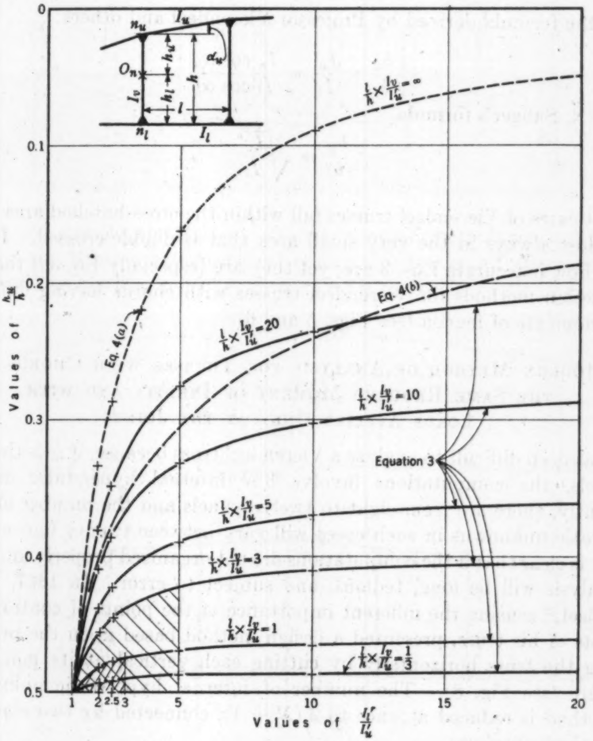

FIG. 7.—COMPARISON OF FORMULAS GIVING POSITION OF POINT OF CONTRAFLEXURE IN THE VERTICALS

This determination of the location of the points of contraflexure in the verticals, or of the distribution of the bending moment between the two chords, is essential. In fact, it makes it possible to determine by experiment whether a design method is accurate or not. Fig. 7 shows the considerable difference between the results given by Eq. 1:

$$\frac{h_u}{h_l} = \frac{\frac{l}{h} \times \frac{I_v}{I_n'} + 6}{\frac{l}{h} \times \frac{I_v}{I_l'} + 6} \qquad (3a)$$

or

$$\frac{h_u}{h_l} = \frac{\frac{l}{h} \times \frac{I_v}{I_n'} + 6}{\frac{l}{h}\left(\frac{I}{I_u'} + \frac{I}{I_l'}\right) + 12} \qquad (3b)$$

and by the formula derived by Professor Vierendeel and others:

$$\frac{h_u}{h_l} = \frac{I_u'}{I_l'} = \frac{I_u \cos \alpha_u}{I_l \cos \alpha_l} \qquad (4a)$$

or Prof. R. Saliger's formula

$$\frac{h_u}{h_l} = \sqrt{\frac{I_u'}{I_l'}} \qquad (4b)$$

Most cases of Vierendeel trusses fall within the cross-hatched area of Fig. 7 and almost always in the very small area that is double-crossed. It will be noticed how inaccurate Eqs. 3 are; yet they are (especially Eq. 3*a*) the basis of many design methods for Vierendeel trusses with chords having different reduced moments of inertia (see Figs. 5 and 6).

THE MODERN METHOD OF ANALYSIS FOR TRUSSES WITH CHORDS HAVING THE SAME REDUCED MOMENT OF INERTIA AND WITH LOADS APPLIED ONLY AT THE JOINTS

It has been difficult to analyze a Vierendeel truss because, if N is the number of panels, the computations involve $3N$ internal hyperstatic unknowns. Frequently, there are from eight to twelve panels and the number of internal hyperstatic unknowns in such cases will vary between twenty four and thirty six. It is clear that if the computations are not organized properly and skilfully the analysis will be long, tedious, and subject to error. In 1897, Professor Vierendeel,[13] sensing the inherent importance of the points of contraflexure in the posts of his truss, presented a design method based upon the principle of dividing the truss horizontally by cutting each vertical at its point of contraflexure (see Fig. 8). The number of internal hyperstatic unknowns by this method is reduced at once to $2(N + 1)$, connected by two statical conditions of equilibrium.

In the thirty years since about 1908, however (especially since the introduction of reinforced concrete), many hyperstatic systems with rigid connections have been introduced and designers have developed many ingenious methods of analysis. The Vierendeel truss, of course, has not been ignored in this development. Unfortunately, methods applying to the analysis of the Vierendeel truss in general have been such as to confirm a popular opinion that the computations are long, difficult, and, consequently, subject to inadvertent errors. In the United States, for example, certain methods of analyzing this truss have been proposed which are very remarkable from an analytical point of view but which do not simplify the problem.

FIG. 9.—DESIGN SKETCHES

Since the two chords have the same reduced moment of inertia, and since the loads are only applied at the panel points, the points of contraflexure in the verticals are at midheight.

---

[14] "La poutre Vierendeel," by L. Baes, *L'Ossature Métallique*, Brussels, October, 1936, and March and September, 1937.

A method may be applied which was developed by K. Kriso[15] and redemonstrated, in another manner, by the writer.[14] An interpretation of general symbols is afforded by Figs. 9(*b*) and 10, in which M_n is the external bending moment; V_n is the external shearing force, at the center of panel *n*; I_{un}, I_{ln}, and I_v are the moments of inertia of the cross sections, respectively, of the upper chord, the lower chord, and the verticals; O_n, O_{n+1}, etc., are the points of contraflexure in the verticals; and W_n, Z_n, and U_n are the three hyperstatic unknowns in panel *n*. The designer selects, as hyperstatical unknowns in each panel, a torque, W_n, and two forces, Z_n and U_n (or the horizontal component, U_n'), and applies them all at the point shown in Fig. 10. For this arrangement, a group of three equations is derived for each panel which can be solved easily due to the essential property that the three hyperstatic unknowns in one of the panels affect only the four members constituting this panel and no other member.

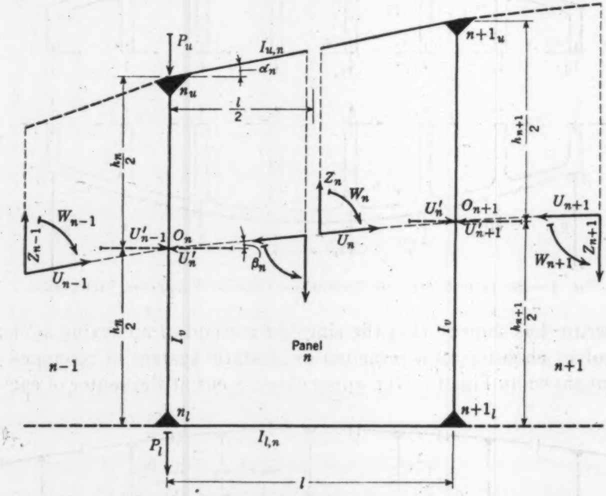

FIG. 10.—EXPLANATION OF SYMBOLS IN PANEL *n*

For each panel, the following equations are obtained, for trusses with parallel chords:

$$-U_{n-1}' + \left(2 + 6\frac{l}{h} \times \frac{I_v}{I_{un}}\right) U_n' - U_{n+1}' = 6\frac{l}{h} \times \frac{I_v}{I_{un}} \times \frac{M_n}{h} \ldots (5a)$$

$$W_n = \tfrac{1}{2} M_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

and

$$Z_n = \tfrac{1}{2} V_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5c)$$

in which M_n and V_n are the external bending moment and shearing force acting on the truss at the midlength of panel *n*.

---

[15] "Stabilité des poutres Vierendeel," by K. Kriso; translated from the German by E. Barbieux and E. Dryon, Paris, France, Béranger, 1926.

For trusses with non-parallel chords, W_n and Z_n are expressed by Eqs. 5*b* and 5*c*, but Eq. 5*a* is replaced by equation:

$$- U_{n-1}' + \left\{ 1 + \left(\frac{h_{n+1}}{h_n} \right)^3 + \frac{3}{2} \times \frac{l}{h_n} \times \frac{I_v}{I_{un}'} \left(\frac{h_{n+1}}{h_n} + 1 \right)^2 \times \left[1 + \frac{1}{3} \left(\frac{h_{n+1} - h_n}{h_{n+1} + h_n} \right)^2 \right] \right\} U_n' - \left(\frac{h_{n+1}}{h_n} \right)^3 U_{r+1}' = \frac{3}{2} \times \frac{l}{h_n} \times \frac{I_v}{I_{ln}'} \left(\frac{h_{n+1}}{h_n} + 1 \right)^2 \left(\frac{M_n + \frac{1}{6} \times \frac{h_{n+1} - h_n}{h_{n+1} + h_n} \times l \times V_n}{\frac{h_n + h_{n+1}}{2}} \right) \ldots\ldots (6)$$

In the case under consideration, two of the hyperstatic unknowns in each panel (W_n and Z_n) become known at once, and it is virtually impossible to make an error in sign.

The entire problem is thus greatly simplified, being reduced to the simple task of solving the system of formulas of the same type as Eq. 5*a* or Eq. 6, which may be called the equations for the two or three U'-values of the panels separated by two adjacent verticals. For all cases, therefore, the solution involves a group of successive linear equations, in stages, starting with two variables, and involving as many formulas as there are panels. Such equations may be solved readily by a slide-rule, and they involve no complications due to successive approximations.

Eqs. 5 and 6 characterize the method and are as important in their connection as the three-moment equation (Clapeyron equation) for the moments in a continuous beam. Their solution is direct and simple as the writer has demonstrated in describing the design of a railroad bridge constructed in Belgium in 1937.[16] In designing a tower only one assumption as to loading is required,[17] and, in the case of a bridge, the method makes it easy to draw the influence line for every element of the computation.[16] Kriso[15] had considered it necessary to develop the equation for every single influence line. Although it is analytically quite remarkable, his study is difficult to read, and for that reason has not attracted attention. The direct solution of Eq. 5 or Eq. 6 for a limited number of positions of a single load is preferable; it demonstrates the simplicity and reliability of that method.

THE MODERN METHOD OF ANALYSIS FOR TRUSSES WITH CHORDS HAVING DISSIMILAR REDUCED MOMENTS OF INERTIA

The preceding method applies in the case when the chords have the same reduced moment of inertia and when the loads act only at the panel points. In all other cases, the method must be completed using the remarkable separating properties of the elastic centers of the panels. This new step was the subject of a thesis presented in 1939 by Emile Robert to the Faculty of Applied Sciences, University of Brussels. The problem is beyond the scope of the present paper; but the method can be used to solve all cases, without making any special assumption, and calling only on very simple first-degree equations, separating the three hyperstatic unknowns of each panel.

CONCLUSION

Personal experience with this subject leads the writer to conclude that:

(1) Regardless of the type of Vierendeel truss, and regardless of the use to which it is put, its analysis is simplest when a section is cut through one of the chord members between two verticals. This method is simple and altogether reliable.

(2) The method described in this paper is based essentially upon the assumption that the points of contraflexure in the vertical members may be determined precisely. Analytical investigation as well as experimental investigation reveal important characteristics pertaining to the location of these points. With the photoelastic method available, an exact theoretical solution can be checked.

(3) The method involves an equation applied to two or three panels which are separated by two adjacent verticals. A given case can be solved readily without successive approximations or other "trick" methods of computation. Such solution involves a complete analysis of the effects of live loads by means of influence lines.

(4) A preliminary design, which in itself is quite accurate, involves the analysis of only one or two conditions of loading.

(5) Thereafter, the computation of a Vierendeel truss, with chords having equal reduced moments of inertia and in which the loads are applied only at the panel points, is shown to be quite simple and free from too broad assumptions. This encourages the writer to believe that this type of truss, without diagonal members, will receive more attention on the part of structural designers in the future.

The writer desires, in this paper, merely to emphasize the existence of an accurate method of designing Vierendeel structures which is simpler, for example, than those currently in use in the United States.

ACKNOWLEDGMENT

The paper was translated into English by L. G. Rucquoi, M. Am. Soc. C. E., to whom the writer wishes to make sincere acknowledgment.

DISCUSSION

Jaroslav J. Polivka,[18] M. Am. Soc. C. E. (by letter).—In the "Synopsis" of his paper Professor Baes states that the points of contraflexure in each vertical of a Vierendeel truss, with chords of equal moments of inertia, are at the midheights of the verticals. This is true only for open-web trusses with inclined chords when the "reduced" moments of inertia of the chords in each panel are equal, as mentioned later in the paper. In other words, when the elastic weights of the chords in each panel are equal:

$$G_u = \frac{l_u}{E\,I_u} = G_l = \frac{l_l}{E\,I} \,..\,(7)$$

In such a case the reactions due to a vertical displacement (Δ, Fig. 11) of the panel intersect at the midheight of the vertical member. (In Fig. 11, C_v, C_u, and C_l are the points of contraflexure in vertical, upper chord, and lower chord members, respectively.)

The occurrence of equal "reduced" moments of inertia in the chords and verticals is quite exceptional and will not be true in most cases encountered in practice. However, except for this restriction, the assumption of fixed points of contraflexure in the verticals will shorten the computations considerably in many cases.

Eq. 5*a* does not involve the influence of shear and direct stress on deformation. This equation can be derived in a general form by introducing the elastic weights of the structural members, and their relationships with the deformations.[19] This further step enables the designer to analyze open-web trusses, com-

[19] "Graphical Analysis of Framed Structures on the Basis of Ellipse of Elasticity," by Jaroslav Polivka, Soc. of Eng. Students, Inst. of Technology, Prague, 1919; also, "Graphical Methods of Analyzing Statically Indeterminate Structures," mimeographed lectures by Jaroslav Polivka, Berkeley, Calif., 1940 and 1941.

posed of members of any shape, and to consider the effect of direct stress and shear.

The general equation is

$$- U'_n \, G_{v,n} \, r^2_{v,n} + U'_n \, G_n \, r^2_n - U'_{n+1} \, G_{v,n+1} \, r^2_{v,n+1} = \Delta_n \ldots\ldots (8)$$

in which $G_{v,n}$ and $G_{v,n+1}$ are the elastic weights of the vertical members at the joints n and $n + 1$ (Fig. 10) and $r_{v,n}$ and $r_{v,n+1}$ are the respective semi-axes of ellipse of elasticity of these verticals. Furthermore, G_n is the elastic weight of the panel n consisting of two verticals and two chords, considered as being isolated from the remainder of the truss; and Δ_n is the displacement due to the external bending moment of the panel n. Eq. 8 expresses the equality of displacements due to internal and external forces. For constant moments of inertia, and for rectangular panels (and neglecting the influence of direct stress and shear on deformation), the values of Eq. 8 become:

$$G_{v,n} = G_{v,n+1} = \frac{h}{E\,I_v} \ldots\ldots (9a)$$

$$r^2_{v,n} = r^2_{v,n+1} = \frac{h^2}{12} \ldots\ldots (9b)$$

$$G_n = \frac{2}{E}\left(\frac{h}{I_v} + \frac{l}{I}\right) \ldots\ldots (9c)$$

and (since $I_{v,n} = I_{l,n} = I$):

$$G_n \, r^2_n = 2\left[\frac{h^3}{12\,E\,I_v} + \frac{l}{E\,I}\left(\frac{h}{2}\right)^2\right] \ldots\ldots (9d)$$

Eq. 5*a* is obtained by substituting Eqs. 9 in the general formula, Eq. 8. This general formula can be used for trusses composed of members with variable moments of inertia such as those that result, for example, when the members are connected by brackets or fillets. This is the most frequent case in practice. Elastic constants for several regular shapes of haunched members are compiled in standard tables. From the values u, v, p, and q tabulated by Walter Ruppel,[20] Assoc. M. Am. Soc. C. E., the constants of the ellipse of elasticity can be computed by the following relationships:[21]

$$G = (p + q)\, G_B \ldots\ldots (10a)$$

$$r^2 = s\,(d - s) \ldots\ldots (10b)$$

$$s = \frac{p}{p + q}\, l \ldots\ldots (10c)$$

and

$$d = (1 - u)\, l \ldots\ldots (10d)$$

The relative displacement (Δ) of the end faces of a structural member, perpendicular to its axis, is caused by a force R passing through the elastic centroid S and having the magnitude

$$R = \frac{\Delta}{G\,r^2} \quad \text{(11)}$$

A general equation similar to Eq. 8 can be derived for panels having members with different moments of inertia.

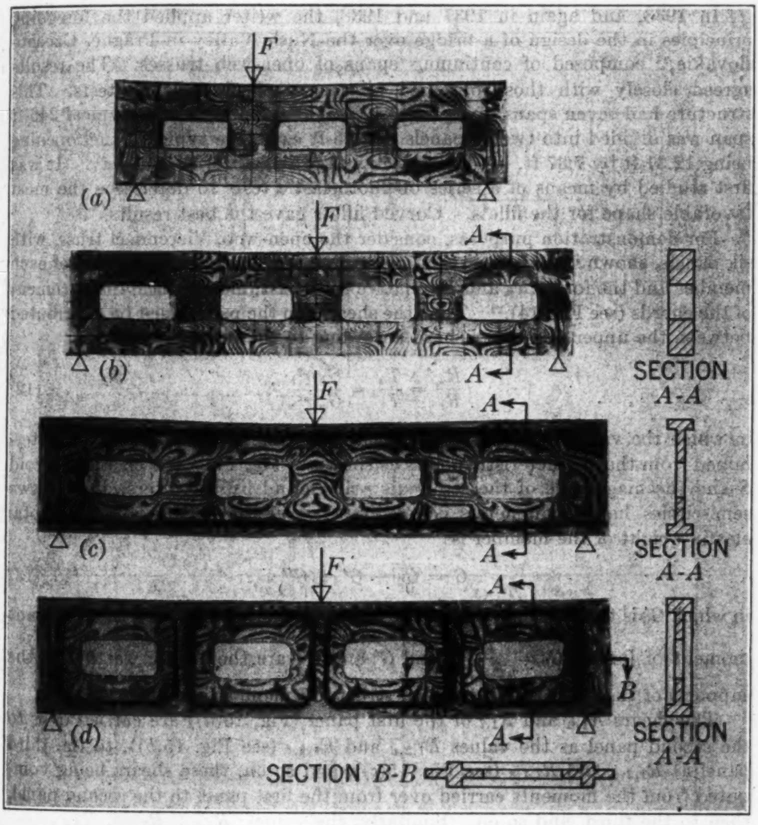

FIG. 12

When the members are relatively slender and the effect of bending is predominant, the points of contraflexure in all members may be obtained by photoelastic investigation and the truss may be considered as statically determinate, having imaginary hinges in all members.[22] The check of the static solution consists in determining the pattern (and even the magnitude, if necessary) of the internal forces by photoelastic investigation.[23] The photoelastic method, however, becomes more complicated whenever the truss consists of deep members. In this case the effect of shear and of stress concentrations, which the fillets cause near the joints, must be considered. The points of contraflexure in the chords approach the joints and in some cases disappear (Fig. 12).

[22] "Analysis of Statically Indeterminate Structures on the Basis of Photoelastic Data," by J. J. Polivka and H. D. Eberhart, Assoc. M. Am. Soc. C. E., paper presented before the Structural Engineers Assoc. of Northern California, San Francisco, August 6, 1940 (mimeographed).

In 1933, and again in 1937 and 1938, the writer applied the foregoing principles in the design of a bridge over the Nusle Valley in Prague, Czechoslovakia,[24] composed of continuous spans of open-web trusses. The results agreed closely with those obtained by means of photoelastic tests. This structure had seven spans, five of which were 246 ft long. The typical 246-ft span was divided into twelve panels of 20.5 ft each, the typical panel opening being 12.31 ft by 7.37 ft. A lower deck was provided for the subway. It was first studied by means of a series of photoelastic tests to determine the most favorable shape for the fillets. Curved fillets gave the best results.

For demonstration purposes, consider the open-web, Vierendeel truss, with six panels, shown in Fig. 13. First determine the characteristic points of each member and the forces R_u and R_l relative to the assumed vertical displacement of the chords (see Fig. 14).[19] Then the shear T in the panel must be distributed between the upper and lower chord according to the ratio

$$\frac{R_u}{R_l} = \frac{T_u}{T_l} = \frac{G_l\, r^2_l}{G_u\, r^2_u} \qquad (12)$$

in which the values G and r, of the elastically restrained members, are determined from the characteristic points as shown in Fig. 14. The elastic centroid S and the magnitude of the semi-axis r are found by the intersection of two semi-circles having diameters equal to $l\,(1 - v)$ and $l\,(1 - u)$. The total elastic weight of the member is

$$G = G_0 + G' + G'' \qquad (13)$$

in which G_0 is the elastic weight of the isolated structural member (for constant moment of inertia $G_0 = \frac{l}{E\,I}$), and G' and G'' are the elastic weights of the supports of the elastically restrained structural member.

The shears $R_{1,u}$ and $R_{1,l}$ of the first panel (Fig. 15(*a*)) are carried over to the second panel as the values $R_{1,2,u}$ and $R_{1,2,l}$ (see Fig. 15(*b*)), to the third panel as $R_{1,3,u}$ and $R_{l,1,3}$ (see Fig. 15(*c*)), and so on, these shears being computed from the moments carried over from the first panel to the second panel, then to the third, and so on. Similarly, the values: $R_{2,1,u}$, $R_{2,3,u}$, $R_{2,4,u}$, $\cdots$ etc., and $R_{2,1,l}$, $R_{2,3,l}$, $R_{2,4,l}$, $\cdots$ etc., are obtained by distributing the shears $R_{2,u}$ and $R_{2,l}$ to the other panels (see Table 1).

It can be seen that the values of the shear distributed to the fourth and following panels are negligible. The total shear in each panel is obtained by

adding all values of the shear occurring at that panel, and those brought over from other panels, with due regard to sign.

A table similar to Table 1 must be compiled for both upper and lower chords. For symmetrical trusses (geometrically and elastically), only one half of these values are computed. The resulting bending moments in the upper chords due to the actual loading producing shears T_1, T_2, T_3, $\cdots$ in the panel 1, 2, 3, $\cdots$ are obtained by adding the expressions

TABLE 1.—SHEAR DISTRIBUTION

Panel	SHEAR DISTRIBUTED FROM THE PANEL IN COL. 1 TO:					
	Panel 1 (2)	Panel 2 (3)	Panel 3 (4)	Panel 4 (5)	Panel 5 (6)	Panel 6 (7)

2	$R_{2,1}$	R_2	$R_{2,3}$	$R_{2,4}$	$R_{2,5}$	(vanishing)
3	$R_{3,1}$	$R_{3,2}$	R_3	$R_{3,4}$	$R_{3,5}$	$R_{3,6}$
4	$R_{4,1}$	$R_{4,2}$	$R_{4,3}$	R_4	$R_{4,5}$	$R_{4,6}$
5	(vanishing)	$R_{5,2}$	$R_{5,3}$	$R_{5,4}$	R_5	$R_{5,6}$
6	(vanishing)	(vanishing)	$R_{6,3}$	$R_{6,4}$	$R_{6,5}$	R_6

$$\frac{T_1}{R_{1,u} + R_{1,l}} \left(M_{1,u} + \frac{R_{1,2,u}}{R_{2,u}} M_{2,u} + \frac{R_{1,3,u}}{R_{3,u}} M_{3,4} + \cdots \right) \qquad (14a)$$

$$\frac{T_2}{R_{2,u} + R_{2,l}} \left(\frac{R_{2,1,u}}{R_{1,u}} M_{1,u} + M_{2,u} + \frac{R_{2,3,u}}{R_{3,u}} M_{3,4} + \cdots \right) \qquad (14b)$$

etc.

Similar expressions are obtained for the lower chords. The addition of the six expressions produces two final expressions (for the upper and lower chords) that are simultaneously valid for all panels. Their general forms are:

$$M_{n,u\,(\text{total})} = a_u\, M_{1,u} + b_u\, M_{2,u} + c_u\, M_{3,u} + \cdots \qquad (15a)$$

and

$$M_{n,l\,(\text{total})} = a_l\, M_{1,l} + b_l\, M_{2,l} + c_l\, M_{3,l} + \cdots \qquad (15b)$$

The values $M_{n,u}$ and $M_{n,l}$ are moments at the joints due to the imaginary forces R_n (Eq. 11), assuming a constant displacement Δ for all chords (for example, $\Delta = 1$).

The moments in the verticals at the joints are then

$$M_{v,n,u} = -\,(M''_{n-1,u} + M'_{n,u}) \qquad (16a)$$

and

$$M_{v,n} = -\,(M''_{n-1,l} + M'_{n,l}) \qquad (16b)$$

The horizontal component of the thrust in the vertical is

$$U_n = \frac{M_{v,n,u} + M_{v,n,l}}{h_n} \qquad (17)$$

Usually the loading is nearly symmetrical and the components U_n must satisfy the condition $\Sigma U_n = 0$. For unsymmetrical truss and loading it will

FIG. 15

be found that $U_n = \Delta U$. In this case $- \Delta U$ must be applied as an external force and its effect combined with the moments due directly to the loading.

If a slight error is permissible, it is not necessary to distribute the shear to the neighboring panels, and the analysis becomes relatively simple. The error decreases rapidly with the number of panels, being less than 5% for the usual type of structure. The adaptation of the method as shown herein makes it possible to analyze highly complicated grid framings of the Vierendeel type.

Conclusion.—The suggestions offered herein extend Professor Baes' analysis to a general form that can be applied to any size, shape, and inclination of truss members and to multiple tiers or stories of panels in the truss, such as may be used for the special design of building frames.

W. A. MILLER,[25] ASSOC. M. AM. SOC. C. E. (by letter).—Experiments along lines somewhat similar to those of Professor Baes, conducted in the Department of Civil Engineering, University of Sydney, in Sydney, New South Wales, Australia, by J. I. Miller,[26] verify the position of the point of contraflexure in the verticals of the Vierendeel truss and substantiate some of the other conclusions of the paper. Using steel spline models and macroscopic deformations, Mr. Miller considered cases with parallel as well as non-parallel chords. The moment of inertia of the verticals was taken about one third that of the upper chord, and that of the lower chord was taken to vary from "equal to" to eight times that of the upper chord. For the range of $\frac{I_u}{I_l}$ from 1 to 4, it was found that the departure of the point of contraflexure in the verticals from midpoint did not exceed 1% of their height. Further examination of frames in sheet celluloid, using microscopic deformations with the aid of a standard deformeter gage, supported the findings using the spline models.

As the main object of the investigation undertaken by Mr. Miller was to develop an approximate and dependable algebraic analysis, applicable to the Vierendeel type of truss likely to be encountered in tower and bridge frames, that analysis was continued, based on the assumptions that the chords were equal (or nearly so) and that the points of contraflexure of the connecting web members occurred at their midpoints.

Using the U-axis (as did the author) and a Z-axis on any vertical in the panel, the hyperstatic unknowns were applied at the intersection and equations in U, W, and Z derived. It was found finally that the selection of the Z-axis to pass through the elastic center of the panel considerably simplified the form of the equations. For the case in which the author's "modified moments of inertia" are equal, these equations reduce to

$$W_n = \tfrac{1}{2} M^0{}_n \qquad \text{(18)}$$

$$Z_n = \tfrac{1}{2} V^0{}_n \qquad \text{(19)}$$

and

$$- h^3{}_{n-1} U'{}_{n-1} + \left[h^3{}_{n-1} + 2 \frac{I_v}{I_n} (h^2{}_{n-1} + h_{n-1} h_n + h^2{}_n) \right] U'{}_n - h^3{}_{n+1} U'{}_{n+1} = 3 l (h_{n-1} + h_n) M^0{}_n \qquad \text{(20)}$$

---

[25] Prof., Civ. Engr., Univ. of Sydney, Sydney, New South Wales, Australia.

[26] From a thesis presented to the University of Sydney, in 1939, in partial fulfilment of the requirements for the degree of Bachelor of Engineering in Civil Engineering.

The symbols are those used by the author, except V^0_n and M^0_n, which are the simple beam shear and moment, respectively, on the vertical through the elastic center. Eq. 20 reduces to Eq. 5*a* for a truss with parallel chords.

A. A. EREMIN,[27] ASSOC. M. AM. SOC. C. E. (by letter).—An interesting review of the historical development of a Vierendeel truss is presented in this paper. In a short time the Vierendeel truss has found wide application, and various materials are used in its construction. Analysis of stresses in this type of truss has revealed many interesting problems in the theory of mechanics, and many computation methods have been developed. Such methods are generally based on previously computed or assumed points of contraflexure in the vertical members. The author has given an interesting illustration of the application of the photoelastic method in determining points of contraflexure in Vierendeel trusses.

In conclusion (1), Professor Baes suggests that, for the analysis of stresses, the upper chord can be assumed cut at each panel. Eq. 5 or 6 may also be developed assuming the truss to be cut at the points of contraflexure in the vertical members. Obviously, the simplicity of the computation method depends not upon the development of the basic equations, but upon the type of redundant forces and their application to the structure. Determination of the stresses with Eq. 5 or 6 requires the solution, simultaneously, of a system of equations with three unknown redundant forces. The author's analysis of stresses may be compared with that proposed by Dana Young, Assoc. M. Am. Soc. C. E., in 1936.[2] Professor Young (and the writer in a discussion of this paper) cited equations for redundant forces in a Vierendeel truss with a factor including the summation of the horizontal redundant forces. The simplicity of computation by either of these types of equations varies with the individual ability of the designer. Furthermore, by algebraic summation, the equations with a summation factor may be easily transformed into the author's type of equation with three unknowns. In conclusion (3) Professor Baes disapproves the method of successive approximations in solving the system of equations for stresses in a Vierendeel truss. However, under the heading "The Modern Method of Analysis for Trusses with Chords Having the Same Reduced Moment of Inertia and with Loads Applied Only at the Joints," he shows that Eq. 5 or 6 may be solved by successive approximations.

The method of successive approximations in analysis of stresses in statistically indeterminate structures has been proved to be very important and has found wide application in the design of structures. Therefore, it scarcely could be considered as evidence that this method is complex. This paper is a valuable contribution.

YVES NUBAR,[28] M. AM. SOC. C. E. (by letter).—In illustrating the application of photoelastic analysis to the study of the distribution of bending moments in the verticals of Vierendeel trusses, this paper by Professor Baes is of timely interest. It contains several formulas and a number of references to comparatively recent research in European technical literature.

---

[27] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[28] Cons. Engr., New York, N. Y.

The writer would appreciate knowing whether the photoelastic test specimens to which the author refers formed a part of the model of a Vierendeel truss, or whether they were isolated specimens subjected to given external axial loads and moments. It will also be interesting to follow the derivation of Eq. 1, in particular whether it was based on further photoelastic tests or exclusively on analytical investigation. In either case, this formula, which appears to have a rather logical structure for cases within the limitations specified by the author, will facilitate greatly the reduction of the general problem to simpler elements, certainly at least for a first approximation. In this connection, it is difficult to understand why Professor Vierendeel's isostatic system of reference (Fig. 8) should not be simpler and of more immediate application than that of the author (Fig. 9), since the points of inflection in the verticals may be assumed located by means of Eq. 1 or other equivalent formulas.

The statement of the author (see heading "Principles of Design for Trusses Without Diagonals: Point of Contraflexure in the Verticals") that "This determination of the location of the points of contraflexure in the verticals * * * is essential" may lead to misinterpretations; it cannot possibly mean what it would convey to the casual reader. Many analyses of Vierendeel trusses have been presented in the technical literature that seem to attach to this determination an undue importance, ascribing to it, explicitly or tacitly, an essential rôle in the solution of such frames. The position taken by Professor Vierendeel himself, as described by the author (see heading "Principles of Design for Trusses Without Diagonals: Point of Contraflexure in the Verticals") illustrates this attitude to some extent. The fact of the matter is that the problem is determinate, and its solution (theoretically, at least, quite simple) requires no further assumptions beyond those commonly accepted in the general theory of rigid frames. The function of a preliminary assumption of the location of

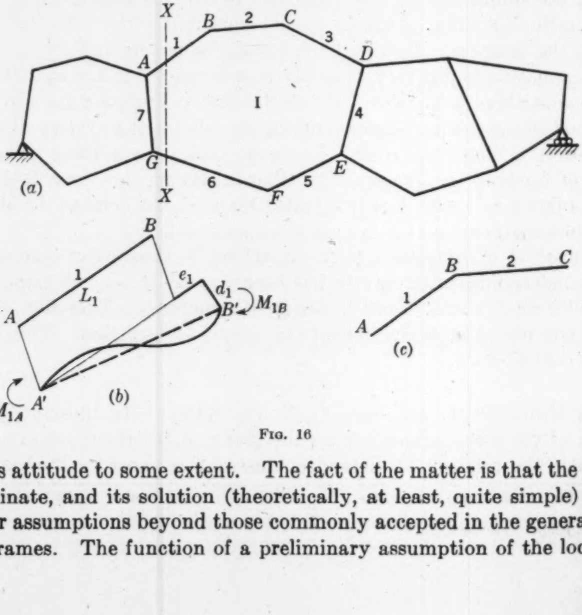

FIG. 16

points of contraflexure is merely to simplify the mathematical analysis involved. More precisely, if N is the number of the panels, it may be shown that the complete solution of a Vierendeel truss of a general type leads to a system of $2(N + 1)$ linear equations of the "six-moment" form (instead of $3(N + 1)$ equations of a more complicated type derived by the great majority of conventional methods of analysis); any assumption as to the location of the points of zero moment in the verticals will simply decompose this system into two other independent systems, each of $N + 1$ equations of the "three-moment" type. This may be brought into formal evidence by means of a different approach to the general problem of rigid frames,[29] summarized partly as follows under four headings, A, B, C, and D:

Consider a Vierendeel truss (or a viaduct tower), of a very general type, composed of single panels of any polygonal shape, joined to each other along a single member (Fig 16(a)) (no claim is here made as to the engineering suitability of such frames, greater generality of results being the only purpose in mind). All symbols and notations entering in the development which follows are condensed in Figs. 16(b) and 16(c). For example, in Fig. 16(b), $A\ B$ is the original position of any member in a given frame; $A'\ B'$ is its position after deformation; M_{1A} and M_{1B} are end moments exerted by the member upon the joints; $R_1 = \frac{d_1}{L_1}$; and $S_1 = \frac{e_1}{L_1}$. Furthermore (see Fig. 16(c)), let $R_{12} = R_1 - R_2$ and $S_{12} = S_1 - S_2$; and in general R_{pq} and S_{pq}, given by similar formulas, refer to any two adjacent members p and q.

A.—Given any panel I, apply the vectors R_{pq} and S_{pq} at each joint as shown in Fig. 17, these vectors being orthogonal but inclined an arbitrary angle γ_1 to the coordinate axes. Three independent relations may be established and stated as follows:

$$\left.\begin{array}{l} \Sigma(\text{the moment about any point, of vectors } R_{pq} \text{ and } S_{pq}, \\ \qquad\qquad\qquad\qquad \text{inclined an angle } \gamma_1) = 0 \\ \Sigma(\text{the moment about any point, of vectors } R_{pq} \text{ and } S_{pq}, \\ \qquad\qquad\qquad\qquad \text{inclined an angle } \gamma_2) = 0 \\ \Sigma(\text{the moment about any point, of vectors } R_{pq} \text{ and } S_{pq}, \\ \qquad\qquad\qquad\qquad \text{inclined an angle } \gamma_3) = 0 \end{array}\right\} \quad (21)$$

all summations being taken around the complete boundary of the panel. Vectors S_{pq} in Eqs. 21 and in Fig. 17 will drop out if axial deformations are assumed to be negligible, at least for a first approximation. In addition, vectors R_{pq} may be assumed written in terms of the end moments of the given members p and q. For instance, for members 1 and 2:

$$R_{12} = \frac{1}{6\,E}\left(\frac{2\,M_{1B} - M_{1A}}{K_1} - \frac{2\,M_{2B} - M_{2C}}{K_2}\right) \ldots\ldots\ldots\ldots (22)$$

in which $K = \frac{I}{L}$. Eq. 22 is derived from the slope-deflection equations applied to members 1 and 2, assumed rigidly connected to each other. Any one of Eqs. 21 may be replaced by $\Sigma\ (R_{pq}) = 0$. Three independent equations such as Eqs. 21 may be written for any panel; they involve no unknowns except end moments (and axial loads or axial deformations when these latter are not assumed negligible). These relations have been termed compatibility equations.

---

[29] See dissertation entitled "Displacements and Stresses in the General Two-Dimensional Framework," presented by the writer to Columbia University, New York, N. Y., in 1941, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

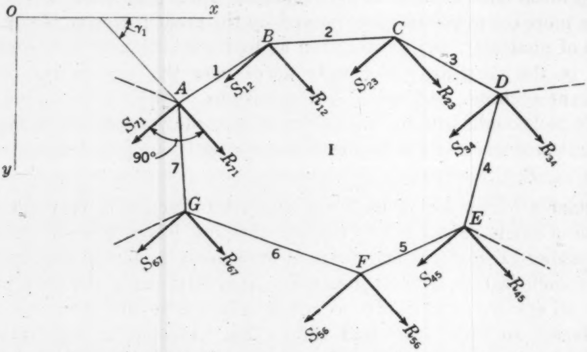

FIG. 17 (THE DIRECTION OF THE ORTHOGONAL VECTORS R_{pq} AND S_{pq} IS THE SAME AT ALL JOINTS)

B.—In addition, three equilibrium equations: $\Sigma X = 0, \Sigma Y = 0$, and $\Sigma M = 0$ may be written at any joint. The joint loading will include:

(*a*) Loads and moments externally applied at the joint;
(*b*) Axial loads in members meeting at the joint;
(*c*) End shears in these members; and
(*d*) End moments in these members.

Since item (*c*) may readily be expressed in terms of (*d*), it is again seen that these joint equations contain no other unknowns but axial loads and end moments.

C.—Returning now to panel *I* of Fig. 16(*a*), the following relations may be written, assuring the equilibrium and continuity of the frame:

(*a*) Three equilibrium equations for the part of the entire structure on one side of line *X X*;

(*b*) Three times three, equals nine, intermediate joint equations for joints *B*, *C*, and *F*; and

(*c*) Three compatibility equations for the panel.

This gives a total of fifteen equations involving the following nineteen unknowns: Five axial loads for members *A B*, *B C*, *C D*, *E F*, and *F G*; and fourteen end moments for all seven members forming the panel. All of these unknowns may then be expressed in terms of $19 - 15 = 4$ of them. This property is general; all unknowns such as the foregoing may be expressed as functions of four of them, regardless of the type of the panel and the number of its sides. The complete solution of the system is not necessary, at this time at least; choose the four end moments of two consecutive web members as parameters and solve only for M_{1A}, M_{3D}, M_{5E}, M_{6G} in terms of them.

D.—Perform a similar operation for each panel; then write equation $\Sigma(M) = 0$ at each joint of the frame at the ends of the web members, such as *A*, *D*, *E*, and *G*. This will yield a system of $2(N + 1)$ linear equations, each involving the six end moments of three consecutive web members. The solution of this system is possible, although often laborious. Any assumption relating the two end moments of each web member (that is, any assumption as to the location of the point of inflection in these members) will break this system of $2(N + 1)$ equations into two other independent systems, each containing $N + 1$ equations between the moments at one end of three successive web members. The similarity of the resulting systems to that of "three-moment" equations is obvious. Such an assumption, if reasonably correct, will lead to quite accurate results which, if desired, may be used to determine a second set of values more closely convergent.

The writer has applied this method to the solution of the symmetrical, five story Kinzua Viaduct.[30] For each panel, the equations listed under heading *C* reduce in this case to only two, as follows:

(*a*) One equilibrium equation;
(*b*) No intermediate joint equation; and
(*c*) One compatibility equation.

These two equations contain only four unknowns: Two end moments for the chord member and one more end moment for each web member in the panel. Proceeding as outlined, a system of five linear equations is obtained between the five end moments of the web members, only two or three of these entering into each equation. The solution of this system is greatly facilitated by the fact that the coefficient of one of the unknowns in each equation is, on the average, twenty times larger than that of the other one or two unknowns. As a result, some appropriate method of solution by successive approximations yields a first set of values, with errors ranging from 1% to a maximum of 5%.

Eq. 6 given by the author is also of the "three-moment" type and will be found very useful in many cases. However, it appears to be predicated upon the following particular assumptions: A straight bottom chord, rectangular or trapezoidal panels of equal spans, equality of reduced moments of inertia for the two chords, equality of moments of inertia for all verticals, and location of the points of inflection at midheight of these verticals. The foregoing analysis is not subject to these restrictions. It is only fair to add, however, that these assumptions will be found almost entirely verified in the greatest majority of actual Vierendeel trusses, and Eq. 6 has a much wider applicability than might appear at first.

Léon G. Rucquoi,[31] M. Am. Soc. C. E.—Professor Baes' candid intent in presenting his paper to American engineers was to obtain the point of view of those in this country who have devoted their attention and studies to the same problem. In this effort the writer was privileged to appear as an intermediary and friend. The fruitful discussion and constructive remarks have certainly fulfilled the author's wish.

CONSUMPTIVE USE OF WATER FOR AGRICULTURE

By Robert L. Lowry, Jr.,[1] M. Am. Soc. C. E., and Arthur F. Johnson,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. B. Debler, Rhodes E. Rule, Edgar E. Foster, Charles H. Lee, Harry F. Blaney, J. L. Burkholder, S. T. Harding, C. S. Jarvis, R. W. Davenport and Gordon R. Williams, and Robert L. Lowry, Jr. and Arthur F. Johnson.

Synopsis

Transpiration and evaporation, together accounting for practically all consumptive use of water, have been shown by experimental investigations to be influenced by climatic factors, of which temperature gives one of the better correlations. Consumptive use in a number of adequately watered irrigated valleys and humid watersheds, representing a wide range in climate, latitude, elevation, and type of crops, is shown in this paper to bear a straight-line relation, within narrow limits, to accumulated daily maximum temperatures above 32° F during the growing season. Factors responsible for deviations from average consumptive use are discussed. The relation of consumptive use to growing-season temperatures offers to the engineer a ready means of estimating probable consumptive use on projects under investigation as an initial step in determining the irrigation requirement at the farm or at the point of diversion. Short descriptions of each area studied, with summaries of annual data, are given in the Appendix.

Introduction

The problems of consumptive use of water have been studied intermittently by engineers of the Bureau of Reclamation since the early years of the organization. The relation of consumptive use to temperatures was first studied in the Bureau in 1920. Other approaches have been made from time to time. Many engineers have collaborated in the studies, and this paper, therefore, is the result of accumulated effort of the organization.

Note.—Published in April, 1941, *Proceedings*.

[2] Engr., Bureau of Reclamation, Denver, Colo.

The study was made for the purpose of obtaining a working basis for estimating the probable annual consumptive use of water on projects under investigation for conditions of full development with an adequate water supply. With consumptive use known, estimates of irrigation requirement may be made by taking into account the effective precipitation and expected losses incident to the diversion and application of the water consistent with the characteristics of the individual project studied. Efforts were directed toward finding a dependable correlation between consumptive use and some factor that influences consumptive use, or some related factor for which records are readily available in most areas, such correlation to be used in estimating the consumptive use on the areas under investigation. Growing-season temperatures were found to be more satisfactory than other factors studied, and this paper discusses their use for this purpose.

The determination of consumptive use for agriculture, in its full sense, involves allowance for consumptive use by nonagricultural areas also. Where nonagricultural use is limited to precipitation, it need not be considered, but, where it is supplied in part from present or potential irrigation supplies, it cannot be neglected. On many projects, control or elimination of nonproductive water uses may determine the feasibility of additional agricultural development. In this study an attempt has been made to evaluate nonagricultural losses contributing to valley consumptive use in order to arrive at the true value of consumptive use for agriculture.

DEFINITION

In a basic sense, consumptive use[3] is "* * * the quantity of water, in acre-feet per cropped acre per year, absorbed by the crop and transpired or used directly in the building of plant tissue, together with that evaporated from the crop-producing land." The Committee's definition of valley consumptive use includes also the consumptive use on the uncropped area and nonrecoverable deep-soil percolation. Valley consumptive use is represented by the difference between annual inflow to the valley (consisting of surface and subsurface movement of water into the valley and of precipitation) and the total outflow therefrom in the same period (consisting of surface and subsurface movement of water out of the valley), with appropriate correction for changes in surface and subsurface storage. For the purpose of this paper, the Committee's definition of valley consumptive use has been modified by the omission of the term "nonrecoverable deep percolation loss" and the substitution of the term "equivalent valley area" for cropped or irrigated area. "Nonrecoverable deep percolation loss" is a form of outflow independent of the factors influencing transpiration and evaporation, the forms of use primarily considered herein. An effort has been made to limit consideration to valleys where deep percolation losses are believed to be negligible. The equivalent valley area in each case comprises the entire area or valley (except for areas consuming no stream flow), reduced to an area consuming water at a rate equivalent to that by the cropped area. Every area considered contains open water or waterlogged areas from which the loss of water is materially higher than on cropped lands, and the abnormal use on such areas counterbalances the incomplete supply on cropped areas. There are often also extensive areas with partial supplies feeding on ground waters or surface wastes from the irrigated areas.

Earlier Investigations

Many studies have been made for the purpose of determining consumptive use of water. These earlier studies usually have been undertaken for special purposes. They reflect many different conceptions of the meaning of consumptive use, and therefore are not generally comparable. Their results must be interpreted in terms of their purposes.

Tank Experiments.—Some of the first experiments on consumptive use were aimed at measuring plant transpiration in relation to growth, and many of these were designed to eliminate surface evaporation. The laboratory experiments of T. A. Kiesselbach,[4] L. J. Briggs and H. L. Shantz,[5] and many others, with tanks and potometers, have demonstrated that, with other factors constant, production of dry matter for any one crop varies in direct proportion to the quantity of water transpired, over a wide range, but that plant efficiency is affected by soil fertility, frequency of cutting, and many other factors. The efficiencies of various plant species were also found to vary widely under similar conditions.

Other experimenters have used tank data as a basis for estimating consumptive use. J. C. Stevens,[6] M. Am. Soc. C. E., used the Briggs and Shantz data for various crops in estimating consumptive use by applying the relation between transpiration and dry matter produced to crop yields. W. C. Hammatt[7] and E. B. Debler,[8] Members, Am. Soc. C. E., and others, have made more direct application by endeavoring to simulate natural conditions. The integration method used by H. F. Blaney,[9, 10] M. Am. Soc. C. E., involves the determination of the consumptive use of various types of crops, native vegetation, and soil surfaces by experiments using undisturbed samples in tanks set in the native habitat of the plants. The rates of use so determined are weighted by the area devoted to that type of use within the study area or valley to obtain the total consumption and weighted average use.

Because of the difficulty of simulating natural conditions and eliminating individual differences, tank experiments were declared by the Duty of Water Committee[3] to be of questionable value. The improved equipment and methods now available remove many of the uncertainties characterizing early tank experiments.

Plot and Farm Experiments.—A large number of plot experiments are constantly in progress at the many federal and state agricultural experiment stations. Although many of these studies are directed toward comparison of plant varieties as to yield, resistance to heat, cold, plant diseases, etc., there have also been many experiments (such as those conducted by J. A. Widtsoe[11, 12] and F. S. Harris[13] in Utah; W. L. Powers[14] in Oregon; M. R. Lewis,[15] M. Am. Soc. C. E., and D. Bark[16] in Idaho; R. G. Hemphill[17] in Colorado; and W. H. Snelson[18] in Alberta, Canada) that have been directed toward use of water. These experiments have shown definite relations between production and application of water under farm conditions and have contributed much to irrigation practice. Generally, they have not attempted to measure deep percolation losses and surface wastes, and so have fallen short of determining consumptive use.

Project Studies.—In some cases, studies of project areas, such as those by W. G. Steward and D. J. Paul[19] and L. Crandall,[20] M. Am. Soc. C. E., in Idaho, have met the requirements for determination of valley consumptive use in method. In general, such studies do not account for uses of water outside the irrigated or cropped area, and the entire use is charged against such area. The increasing necessity for conservation of water resources requires that use of water by nonproductive areas be considered in relation to irrigation efficiency, and in the future most studies must be made valley wide.

Valley Studies.—Many studies of valley consumptive use have been made using inflow-outflow methods and the data submitted as testimony in water-right adjudications and interstate suits. Among these may be mentioned the following: Sevier Valley, Utah[21]; Cache la Poudre Valley, Colorado[17]; Cache la Poudre and South Platte valleys, Colorado, and Little Laramie Valley, Wyoming[22, 23]; Arkansas Valley, Colorado[24]; San Luis Valley, Colorado[25];

Truckee River, Nevada[26]; Owens Valley, California[27]; San Gabriel Valley, California[28]; Columbia River and its tributaries, Washington-Oregon[29]; and Rio Grande in Colorado, New Mexico, and Texas.[10] The results from some of these studies have been used in this paper. Others were either incomplete or involve valleys with an inadequate water supply and so have been excluded.

The methods and results of these studies are not discussed herein as many of the reports are readily available. Several of the studies are discussed in Society publications and reviewed in the Committee Report.[3]

INFLUENCE OF METEOROLOGICAL FACTORS

Although small-scale experiments using tanks, potometers, etc., for determining consumptive use are of questionable value in some cases, they have been of great value in pointing out the importance of transpiration and evaporation as the chief processes in consumptive use and the influence on these phenomena of meteorological factors. Considerable research has been directed toward the determination of both transpiration and evaporation.

The potometer experiments on transpiration of plants of various kinds conducted by Messrs. Briggs and Shantz[30, 31] are among the most extensive of their kind. They indicate a very close correlation between transpiration and meteorological phenomena, including evaporation from water surfaces, air temperatures, solar radiation, and wet-bulb depression readings. Experiments on sorghum, wheat, oats, rye, alfalfa, and pigweed, which cover a wide range of rates of water use, all show similar changes in hourly rate of use throughout the daily cycle.[32] Experiments on the rate of transpiration of tules at the Prado Station in California[33] show similar hourly cycles for transpiration, evaporation, and temperature, of air and of water.

The latter experiments showed that 93.5% of the total daily transpiration occurred between 9 a.m. and 9 p.m. Observations of ground-water levels in an alfalfa field in the Escalante Valley, Utah,[34] showed a distinct lowering of the water table during daylight hours and a recharge at night. Similar results were obtained[35] for native vegetation in the Middle Rio Grande Valley. Experiments on evaporation[36] at Fort Collins, Colo., showed that two thirds of the daily evaporation occurs during daylight hours. Obviously, solar radiation or some secondary phenomenon connected with sunlight is an important factor in both transpiration and evaporation. In fact, the Escalante Valley experiments showed a marked decrease in transpiration on cloudy days from that on clear days.

The Briggs and Shantz experiments over long-time periods show the variation in rates from day to day as affected by changes in solar radiation and temperatures. A comparison of daily changes in solar radiation and temperatures indicates that the former is a function of the altitude of the sun and thus varies with the seasons, whereas the latter (temperature), which is dependent upon absorption of heat by air and earth, and the circulation of the air, lags behind the seasons. Although solar radiation gives one of the best correlations with transpiration and evaporation, growing-season temperatures more nearly parallel the cycle of plant growth. Fig. 1 shows clearly the relation of consumptive use to the monthly mean of maximum daily temperatures above 32° F for the Mesilla Valley in New Mexico, one of the few areas for which monthly values of consumptive use are available. Maximum daily temperatures are used as being more representative of daylight hours when most of the transpiration occurs.

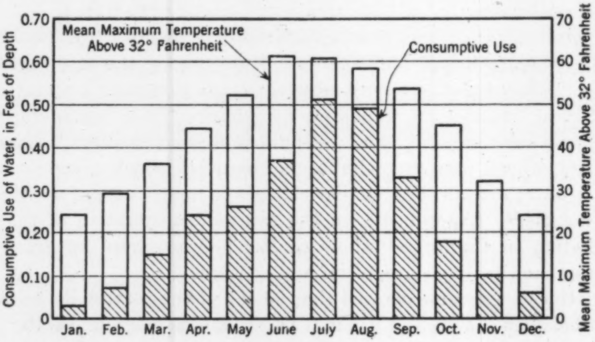

FIG. 1.—COMPARISON OF MONTHLY DISTRIBUTIONS OF CONSUMPTIVE USE AND MEAN TEMPERATURES ABOVE 32° F

Consumptive use (see Fig. 1) is relatively lower with respect to temperature in winter than in summer and has a different distribution in the spring than in the fall. These variations are produced by differences in plant water requirement as related to plant development. In winter, perennial plants are practically dormant and annual plants are entirely so. As spring advances, annual crops are seeded and all plants increase in size. As their leaf area enlarges, their water requirements increase, and reach a maximum soon after maximum temperatures pass the peak of the season. In the fall, water requirements drop rapidly as the function of the plant is transferred from growth to processes of ripening and reproductive development; and growth practically ceases with harvest or with the onset of sub-growing temperatures. The pronounced lag in consumptive use noted in May is due in part to the cutting of alfalfa and the harvest of winter crops and in part to the preparation of seedbeds for planting cotton and other summer crops. In the Mesilla Valley 91% of annual consumptive use and 85% of annual evaporation occur during the eight-month growing season, March to October.

Hedke Method of Estimating Consumptive Use.—The method of estimating consumptive use derived by C. R. Hedke,[37] M. Am. Soc. C. E., is based on the principle that each crop requires a definite quantity of heat above its germinating temperature to bring it to maturity, and that moisture and plant food are required in proportion to the heat utilized. Basing his study on the years 1916 and 1917 and the estimated normal year, in the Cache la Poudre Valley, Mr. Hedke accumulated mean daily temperatures, in degrees Fahrenheit above the germinating temperature, for each crop produced in the valley over its period of growth; and he weighted each crop total by the area devoted to that crop. The weighted average consumptive use of heat per cropped acre was then plotted against consumptive use of water in acre-feet per cropped acre to obtain a correlation curve. In determining consumptive use of water, 50% of the annual precipitation was added to the measured stream depletion. The ultimate object of the method was apparently a guide for estimating stream depletion in other valleys, and it was assumed that effective moisture not obtained from precipitation must be supplied from stream flow. Mr. Hedke assumed that precipitation, falling on the soil surface, evaporates twice as rapidly as normal soil moisture drawn from depth. He did not allow for variations in ground-water storage in computing consumptive use, and he charged the total valley use to the cropped area without regard to relative uses by non-cropped land.

METHOD OF STUDY

The present study, like that of Mr. Hedke, is predicated on correlating consumptive use of water to effective heat during the growing season; but in details it departs widely from the Hedke method. Of necessity the study has been confined to a rather limited number of areas for which essential data are available. These data have been utilized in accordance with a method of procedure found by trial to give the most satisfactory results.

Measurement of Use of Water.—On each area used in the study, adequate records or estimates were obtained of surface inflow to, and outflow from, the area; of changes in surface and ground-water storage, if appreciable; and of precipitation. The study was confined to areas believed to have negligible or compensating underground inflow and outflow. Where ground-water storage was considered to be fairly stable from year to year, no correction for changes in such storage was deemed necessary, as any error due to this factor is practically eliminated from the mean consumptive use over a period of several years. Precipitation was computed by weighting the recorded quantity at available stations by the area nearest each station. The full year, rather than the growing season, was used as a basis of study in order to eliminate the effect of seasonal changes in water table and soil moisture, which are affected by the surplus or deficiency in precipitation compared with consumptive use. For the sake of uniformity, the calendar year was used for all areas, although it is perhaps less satisfactory on some areas than some other operating year for securing accurate measurements because of unfavorable distribution of precipitation, snow storage, high stream discharge, or ground-water changes. As these factors vary with the locality, no one period would be satisfactory for all areas.

---

[37] "Consumptive Use of Water by Crops," by C. R. Hedke, New Mexico State Engrs. Office, July, 1924 (unpublished).

Correction for Years of Short Water Supply.—In most of the areas studied, shortages of water supply occurred in one or more years of the period of record. Omitting the records of the dry years in arriving at mean values for each area introduces errors in those cases where no records of ground-water storage are available because it is usually withdrawn in dry years, through consumptive use and natural drainage into streams, and is replaced in wet years. When dry years are omitted, ground-water recharge enters into the mean as consumptive use. It was believed preferable, therefore, to include all years of record in the mean and to add a correction factor to the water supplies in low years sufficient to make them adequate. From an inspection of the records of inflow and consumptive use in dry years, it appears that consumptive use deviates from the mean much less, relatively, than does total inflow. In the humid regions the lessened rainfall is more fully used because the soil capacity of the root zone is overtaxed less frequently with reduced escape of water to the underlying water table. Runoff is also relatively less. In the irrigated areas, the same results are achieved by reduced irrigation applications and reduction in surface waste. Withdrawals from ground water both for plant life and through natural drainage are important in such years. In succeeding wet years there is a recharge of depleted ground water.

Equivalent Area.—Instead of referring use to cropped area or to gross valley area as a basis for computing consumptive use (as has been done frequently), an estimate was made of the area, within the limits defined by points of measured inflow and outflow, consuming water at a rate equivalent to that on the cropped area or land representative of prevailing conditions in the valley. In irrigated valleys, high areas consuming only precipitation and contributing a negligible quantity of runoff were omitted. Corrections were made in the remaining area, as believed advisable, to compensate for unbalanced areas in swamp land consuming water at a higher rate than cultivated land and in natural vegetation adjacent to irrigated areas consuming less water than cultivated land. Although these corrections are a matter of judgment, the net effect is small, since the cropped land in most agricultural valleys amounts to 85% or more of the gross area.

Correction for Variations in Irrigated Area.—In irrigated valleys the acreage actually irrigated and cropped may vary from year to year. After full development has been reached, fluctuations in area are normally so small that they may be neglected in computing consumptive use; but, if economic conditions cause major changes, the variations in area should be considered. Since

1933 the program of the Agricultural Adjustment Administration (AAA) in many localities has effected reductions in the area devoted to certain staple crops and has freed the land for other uses. In some cases land has been removed from cultivation and has received little or no regular irrigation. Where the cropped area in a given valley has been reduced during the period of study, consumptive use values in the affected years have been computed on an equivalent area, resulting from a deduction of one half the area temporarily out of cultivation that year, on the theory that a limited weed growth and soil evaporation would still occur. This is equivalent to fixing the consumptive use on the fallow land at one half that on cropped land.

Effective Heat.—As used in this paper, the term "effective heat" is the accumulation, in day-degrees, of maximum daily temperatures above 32° F during the growing season. This measure of heat was decided upon after comparative studies had been made using mean daily, as well as maximum, temperatures with bases both above and below 32°. The choice of the maximum temperature is in line with experiments showing that transpiration and evaporation take place almost entirely during the daylight hours, when temperatures are normally higher than at night. Although evaporation of moisture from soil and other surfaces continues at a low rate during the winter, transpiration is almost entirely confined to the growing season. During the winter season, maximum temperatures are frequently considerably above the freezing point even when minimum temperatures prevent plant growth. Because of this break in the relation of consumptive use to heat, a much better correlation is obtained between annual consumptive use and accumulated growing-season heat units than with total annual heat units.

Length of Growing Season.—The growing season is frequently considered the time between killing frosts. For annual crops the growing season is necessarily shorter than the frost-free period, in order to permit planting in the spring after danger of frosts is past and to permit maturing and possibly harvesting before the first serious frost in the fall. For most perennial crops, growth starts as soon as the maximum temperature rises far above the freezing point for any extended period of days and continues in spite of later freezes throughout the season—and sometimes for many weeks after the first so-called killing frost. In the spring, and to a less extent in the fall, daily minimum temperatures may fluctuate 1° or 2° above and below 32° for several days before remaining above or below that point, even though the temperature for most of the day is quite warm and the hardier crops are able to grow unharmed by the few hours of subfreezing temperature. In fact, many hardy crops, and especially grasses, mature although temperatures drop below freezing at frequent intervals throughout the summer.

In order to define the limits of the growing season more definitely than the dates of the latest and earliest frosts, minimum temperature data were smoothed by obtaining twice-repeated five-day moving averages, equivalent to applying the expression, $\frac{a + 2b + 3c + 4d + 5e + 4f + 3g + 2h + i}{25}$, to the consecutive daily minimum temperatures (represented in the expression by letters) and offsetting the result to the middle day of the series to maintain proper phase. The ends of the growing season are thus defined by the dates between which the smoothed temperatures remain above 32°.

Valley Areas Studied

The work of the Bureau of Reclamation is concerned primarily with the arid West where agricultural development is dependent upon irrigation. In this paper, available studies on consumptive use were utilized. Some of them were on Bureau of Reclamation projects, constructed or under investigation; others were studies by various agencies in connection with local and interstate litigation. Many other areas were examined but discarded for lack of adequate records.

As a check on the validity of the conclusions reached for irrigated areas, the study was extended to a number of valleys in the humid regions of the United States and to one mountain basin in Colorado, where an essentially adequate water supply is obtained from precipitation. In these cases the entire watersheds are included in the study areas, and consumptive use is computed by deducting outflow from precipitation. Consumptive use in these humid valleys was found to vary with effective heat of the growing season in exactly the same manner as in irrigated arid valleys.

Table 1 lists the various valley areas used, with comparative data on area, elevation, and number of years of study. Fig. 2 shows the average consumptive use on each area for the period of study, plotted against the corresponding average effective heat. A brief description of each area, with annual data on consumptive use, effective heat, and source of basic information, is given in the Appendix.

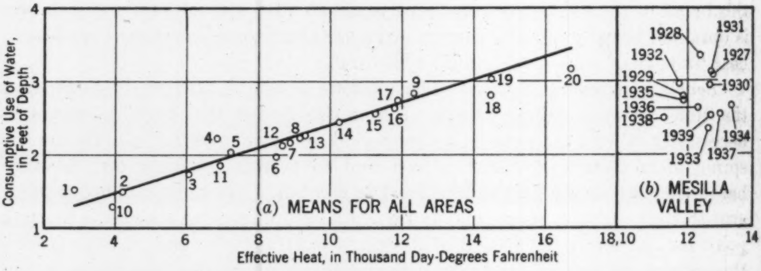

FIG. 2.—RELATION OF CONSUMPTIVE USE TO EFFECTIVE HEAT (NUMBERS IDENTIFIED IN TABLE 1)

The areas included in the study represent practically the entire range of growing conditions and types of agriculture found in the United States. Climatic conditions range from arid to humid and from frigid to subtropical, growing seasons range from a few days to the entire year, latitudes range from near the northern to the southern boundaries of the nation, and altitudes from near sea level to over 10,000 ft; crop diversification varies from the mountain meadow hay and alpine forests to cotton and citrus fruits. Notwithstanding the wide differences in crops, the relation between consumptive use and effective heat is maintained closely.

ANNUAL VARIATIONS IN CONSUMPTIVE USE

The plotted points of Fig. 2(*a*) show only a small deviation from the curve. When individual years instead of means are plotted, a rather wide variation is noted. As an example, Fig. 2(*b*) shows the relation of consumptive use to effective heat for the Mesilla Valley, New Mexico, for the period of study 1927 to 1937. Measurements on this valley are probably more complete than on other areas studied, and yet deviations from the mean consumptive use amount to as much as 18.7% and deviations from the mean effective heat to 6.4% for individual years.

Variations from the mean may arise from many causes, among which are: (1) Inaccurate records of discharge; (2) inaccurate estimates of ground-water storage changes; (3) inadequate precipitation and temperature records; (4) differences in occurrence and intensity of precipitation, and variability of temperatures, wind, hail, cloudiness, humidity, etc.; (5) inaccuracy in estimating the area equivalent in rate of use to the cropped area; and (6) changes in crop distribution, damage by plant diseases, insects, animals, and weeds.

In many valleys where the stream flow is quite large as compared with stream depletion within the valley, small percentages of error in stream measurement may be reflected by large discrepancies in estimates of consumptive use.

Corrections for surface storage can be made accurately where reservoir-capacity data and storage records are available but, because of the heterogeneous nature of most valley fills, it is difficult to evaluate ground-water storage changes. Water-level measurements from only a few wells may be misleading. Application of a single yield coefficient for converting differences in depth into storage changes gives a rough estimate at best and may not reflect actual conditions, especially where changes in water-table levels are not uniform throughout the valley.

Inadequate coverage by precipitation stations may result in wide discrepancies where rainfall distribution tends to "spottiness." Even with adequate coverage, variations still will prevail where there are marked differences in seasonal distribution. For the same annual precipitation, soil-surface evaporation will be much greater in a year when there are numerous light showers than when there are only a few heavy rains which penetrate deeply and also produce considerable surface runoff. The distribution between summer and winter also affects consumptive use, as evaporation is higher in summer than in winter.

Temperatures do not usually vary greatly over a valley area, and for that reason inadequate coverage by recording stations is not likely to be an important source of error in estimating effective heat. Differences in temperature from year to year will normally cause corresponding differences in consumptive use; but changes in consumptive use may vary widely from the relation exhibited by valley means (see Fig. 2(*a*)) because of changes in temperature distribution and plant efficiency. Abnormally low temperatures may retard plant development, or unusually high temperatures may cause plants to become dormant. The latter effect is especially noticeable in the case of the southern study areas where consumptive use is actually reduced in the hotter years, even when the water supply is adequate. Consumptive use may vary widely in years of equal accumulated temperatures because of deviations from the normal seasonal distribution, as transpiration is influenced by the area of leaf surface and plant functional requirement (both related to stage of maturity), as well as by temperature. The effect of increased wind movement is normally to increase evaporation; and the effect of increased humidity and cloudiness is to reduce it. Hail may damage crops and thus reduce, materially, their rates of transpiration.

The annual consumptive use varies with type of management and land use, which are influenced by economic factors. These factors may change crop distribution and methods of irrigation. Thus, a change from grain to alfalfa will increase transpiration. Consumptive use by native vegetation on noncropped areas may be expected to remain more or less constant from year to year where the water supply is adequate, but surface evaporation will increase in wet years because of the increase in area of water surface and moist soil.

In irrigated valleys there is usually a lavish application of irrigation water when the supply is abundant; and there is a consequently larger amount of waste and return flow available for nonproductive consumption, as well as an increased soil evaporation on the cropped lands. For these reasons the equivalent valley area is seldom a constant; actually, it increases in wet years and decreases in dry years. Plant diseases and pests reduce consumptive use by inhibiting plant growth. The spread of noxious weeds may reduce the area irrigated if crops cannot be grown in infested areas. Indirect results of infestation may appear in widespread changes in crops.

Most of the factors mentioned fluctuate from year to year. Consumptive-use studies continued over a series of years may be expected to eliminate most of the inaccuracies in measurements and smooth out short-time trends due to changes in crop distribution and other factors.

APPLICATION

An essential feature of the water-supply investigation of an irrigation project, whether it is an undeveloped tract needing a full supply or a developed project needing supplemental water, is the determination of its water requirement. Annual consumptive use is a convenient approach in this determination. From the relation developed in this paper it is possible to estimate consumptive use from temperature data, which are usually available. The crop irrigation requirement may then be estimated by deducting from consumptive use that part of the annual precipitation that it is estimated will be consumed. The farm delivery requirement then may be estimated by adding to the crop irrigation requirement an allowance for deep percolation and surface waste incident to application of water to the land, consistent with anticipated irrigation practice under local conditions. The diversion requirement then may be estimated by providing for canal and lateral operation waste and losses in transit from stream or reservoir to the farm. In case the project is to be devoted chiefly to a single crop, differing materially in its water requirements from the average requirements common to the temperature conditions of the project, the consumptive use estimated from the relation curve may be corrected as required. Although the determination of the project-diversion requirement leaves much to judgment after the proper consumptive use has been adopted, a mass of experimental data on the other factors is available to guide the investigating engineer in his determinations.

ACKNOWLEDGMENT

Data for this paper were secured from various sources, and where possible the source has been stated. Data on land use in the humid areas were obtained from U. S. Census reports, or from personal knowledge, and climatic and runoff data used in connection with area studies, not specifically acknowledged, were obtained from publications of the Weather Bureau and Geological Survey, respectively. Appreciation is expressed for the advice and assistance of R. I. Meeker, M. Am. Soc. C. E., and R. J. Tipton, Assoc. M. Am. Soc. C. E., in the conduct of this study.

This paper was prepared in the course of official duties for the Bureau of Reclamation of which John C. Page, M. Am. Soc. C. E., is commissioner, and S. O. Harper, M. Am. Soc. C. E., is chief engineer. The work was done under the immediate supervision of E. B. Debler, M. Am. Soc. C. E., hydraulic engineer. Many of the project superintendents and investigating engineers of the Bureau of Reclamation have assisted in supplying valuable data. Assistance in making studies and computations was rendered by assistant engineers R. R. Reed, Jun. Am. Soc. C. E., and C. L. Myers; and junior engineers I. F. Richards and C. E. Mohler, Juniors, Am. Soc. C. E., and R. I. Brasaemle, H. Y. Hsu, and J. S. Fulton.

APPENDIX

DESCRIPTION OF AREAS STUDIED

New Fork Valley, Wyoming.—The valley is in the upper Green River Basin above Pinedale, Wyo., at an elevation of about 7,400 ft. It has a gross area of 25,400 acres, of which 16,650 acres in meadow hay and pasture are irrigated. A part of the remainder is in sagebrush and a part in willows and seeped alkali land. The equivalent area is estimated at 25,000 acres. The climate is severe in winter. Summer temperatures reach 90°, but frosts frequently occur at night in every month. Precipitation averages 10.2 in., of which 4.3 in. fall in the months of May to August. Irrigation by wild flooding is practiced, and the area always has adequate water. Consumptive-use studies were made by the Bureau of Reclamation in 1939 (Table 2, No. (1)) and include inflow and outflow measurements and precipitation. Ground-water storage, as indicated by test wells, did not show any change for the year, and ground-water movement is believed to be small. Because of the prevalence of summer frosts, the effective growing season is doubtless longer for the type of crop grown than that computed for the study.

Michigan and Illinois Rivers, North Park, Colorado.—The study area includes the narrow valley of the Michigan River between the Haworth School and Cowdrey and the tributary valley of the Illinois River below Rand, in North Park, near Walden, Colo. Grass and hay, covering 35,250 acres, are the only crops. The remainder of the area is in willows and water surface. The equivalent area is estimated at 43,000 acres. The average elevation is about 8,300 ft. The climate is rigorous. Temperatures range from − 49° to 109° with a May-to-September average of 53°. The frost-free period is about

60 days. Annual precipitation averages 10 in., about one half falling during the growing season. The meadows are irrigated by flooding until hay is cut, and the supply obtained from the Michigan and Illinois rivers is adequate. Data (Table 2, No. (2)) were supplied by the Colorado Water Conservation Board.[38] Winter runoff not covered by records was estimated. Ground-water storage as shown by well measurements was essentially the same each year with no movement into, or out of, the basin.

[a] U = consumptive use, in ft; and H = effective heat, in degree-days (F).

Southwest Area, San Luis Valley, Colorado.—The area includes the valley lands tributary to the Rio Grande on the west, amounting to 400,000 acres. The topography is comparatively flat—about 7,750 ft in elevation. About 56% of the area is farmed, principally to hay, grain, and potatoes. The equivalent area is estimated at 390,000 acres. The climate is moderately warm, dry, and windy during the short summers, and cold in winter. Precipitation averages about 7 or 8 in. per yr, about 65% of it in the growing season. Water for irrigation is supplied from the Rio Grande and its tributaries. Subirrigation is practiced widely. Consumptive use has been determined by a number of agencies from inflow-outflow measurements, but the present study (Table 2, No. (3)) includes only the 1936 determination by the Bureau of Agricultural Engineering as a part of the Rio Grande Joint Investigation.[10]

West Tule Lake, Klamath Project, California.—The area includes land under the J-1 lateral of the Tule Lake Division of the Klamath Federal Reclamation Project lying within the dikes west of Lost River. The mean elevation is about 4,150 ft. The effective area is estimated at 6,300 acres, of which 5,700 acres have been irrigated in recent years. The soil is a sandy lake-bed deposit and drains well. Alfalfa, cereals, and potatoes are the principal crops. Temperatures vary from sub-zero to 100°. The growing season is about 140 days. Precipitation averages about 8.5 in., most of which occurs in the fall and winter. Irrigation is necessary for agriculture, and an adequate supply is obtained from the Lost and Klamath rivers. Inflow is measured in the supply lateral and outflow at drainage pumps. Ground-water storage is maintained nearly constant by well-regulated drains; and, because of the small differential between Lost River and drains, little underground flow is believed probable. Data (Table 2, No. (4)) were furnished by the Klamath Project office and from the report by J. R. Iakisch,[39] Assoc. M. Am. Soc. C. E.

---

[38] "Jackson County Investigations—Special Studies on Consumptive Use," by C. L. Patterson, Colorado Water Conservation Board, 1940 (in course of preparation).

Garland Division, Shoshone Project, Wyoming.—The area consists of 48,400 acres of fairly level bench land, 4,200 to 4,600 ft in elevation, lying north of the Shoshone River near Powell, Wyo. Although only 30,000 acres were irrigated at the time of the study, 41,900 acres are irrigable and estimated to consume water equivalent to the rate on cropped land. Soils vary from sand to clay. About 50% of the cropped area was in alfalfa, the remainder being mainly grain, sugar beets, and potatoes. Inflow is supplied by the Garland Canal and some storm runoff; outflow is measured in the Frannie Canal, Bitter Creek, and river drains. Complete records of inflow and outflow are not available in any one year, but the missing data (storm inflow, and drains to river and Bitter Creek) have been estimated from measurements available in other years. Deep percolation losses are believed negligible. The water supply was average in two years, abundant in one, and deficient in one. Data in Table 3, No. (5), were supplied by the Bureau of Reclamation project office and from reports by H. H. Johnson.[40]

[a] U = consumptive use, in ft; U_p = computed consumptive use; U_r = corrected consumptive use; and H = effective heat, in degree-days (F). [b] Dry year corrected by a quantity considered adequate to insure normal consumptive use. [c] Non-irrigable watersheds; Nos. (5) and (7) are irrigable.

North Platte Valley, Wyoming, and Nebraska.—The study area includes the valley between Whalen, Wyo., and Lisco, Nebr. This valley has an average elevation of 4,100 ft, a length of 120 miles, and a width of 7 miles. It includes an equivalent area estimated at 462,000 acres, which includes the North Platte Federal Reclamation Project and private lands. The bottom soils are black loam, the terrace soils sandy loam. There is a considerable area of river bed, reservoir surface, and seeped bottom land. Part of the area once seeped has been drained. The underlying Brule clay precludes deep percolation, and as the channel is cut into this material there is little underflow at the river gaging stations. The area is in general crops with alfalfa, sugar beets, and cereals prevailing. Temperatures vary from sub-zero to more than 100°. The growing season is about 165 days. Precipitation averages about 17 in., of which 75% falls in the growing season. Additional water is supplied by irrigation from the North Platte River and from reservoir storage. The supply has been adequate except in years such as 1931 and 1934. Records of inflow and outflow (Table 4, No. (6)) were corrected for changes in surface storage, but no correction for ground storage was considered necessary. Records were obtained from the North Platte Project Office.

[a] U = consumptive use, in ft; U_p = computed consumptive use; U_r = corrected consumptive use; and H = effective heat, in degree-days (F). [b] Dry year corrected by a quantity considered adequate to insure normal consumptive use. [c] Years of reduced acreage, U_r based on equivalent area less one half of reduction in area. [d] Non-irrigable watershed; Nos. (6), (8), and (9) are irrigable.

Mason Creek Area—Boise Project, Idaho.—The area includes 13,570 acres of the Pioneer Irrigation District in the Boise Project of the Bureau within the Mason Creek drainage unit near the towns of Caldwell and Nampa. The elevation is about 2,500 ft and the topography fairly flat. It is all irrigated except for right of ways and farmsteads. At the time of the study it was more than 50% in alfalfa and clover hay, and the remainder was largely grain. An adequate water supply is furnished through the Phyllis Canal from Boise River and Arrowrock Reservoir. Precipitation amounts to about 10 in. per yr, little of it occurring in the growing season. .Outflow is measured in the various drains and by observing the ground-water changes in 55 wells. There is apparently little difference in ground-water inflow and outflow as the area is surrounded with uniformly well-drained irrigated land (see Table 3, No. (7)).[19]

Uncompahgre Valley, Colorado.—The valley is at the foot of the San Juan Mountains in the Gunnison Basin and includes Montrose and Delta, Colo., at an average elevation of about 5,500 ft. Most of the area is in the Uncompahgre Federal Reclamation Project. It has a gross area of 169,000 acres, of which 86,500 acres are irrigated and cropped to alfalfa, cereals, sugar beets, and onions. The soil is heavy, much of it has been seeped, and a part is affected by alkali. From a field study of the non-cropped land, the area equivalent in rate of use of water to the cropped land is estimated at 137,700 acres. Temperatures range from −25° to 102° with an average during the growing season of about 67°. The growing season is about 145 days. The average annual precipitation is 9 in., of which about one half falls in the growing season. Abundant water for irrigation is obtained from the Uncompahgre and Gunnison rivers and the Taylor Park Reservoir. Ground-water inflow and outflow are believed to be small. Corrections were made for ground-water storage change effected by drainage operations. Data were secured in a cooperative study by the Bureau of Reclamation and Colorado Water Conservation Board (see Table 4, No. (8)).

Mesilla Valley, New Mexico-Texas.—The Mesilla Valley is one of the many narrow valleys of the Rio Grande. It extends from Fort Seldon, New Mexico, almost to El Paso, Tex., and comprises the Leasburg (N. Mex.) and Mesilla divisions of the Rio Grande Federal Reclamation Project. The valley bottom is flat and varies in elevation from 3,700 to 3,900 ft. Of the gross area of 109,000 acres, about 77,000 acres are cropped, principally to cotton and alfalfa, 13,000 acres are in native vegetation, and the remainder in miscellaneous uses. Studies by the U. S. Bureau of Agricultural Engineering[10] in 1936 indicate the consumptive use by the non-cropped land to be essentially at the same rate as by the cropped land except in the case of areas temporarily out of cultivation, which vary from year to year. An equivalent area of 109,000 acres has been used except for the years noted in Table 4, No. (9). Temperatures range from −8° to 106° with an annual mean of about 60°. Annual precipitation is about 8 in., two thirds falling in the 240-day growing season. Irrigation water is supplied from the Rio Grande with storage in Elephant Butte and Caballo reservoirs. The data in Table 4, No. (9), were supplied by the Rio Grande Project Office, and for the years 1927 to 1936 were included, in uncorrected form, in the study by Mr. Debler.[41] The effect of annual differences in the factors affecting consumptive use of water is well illustrated by the annual variations in consumptive use in the Mesilla Valley.

At Agricultural College, N. Mex., precipitation in 1931 was the highest of the years of study and consumptive use of water second highest. In 1935 precipitation was second highest in total, but approximately one half of the total fell in one day and consumptive use was below the average of the period. In 1928, the year of greatest consumptive use, precipitation occurred in many light rains. The year of least rainfall, 1933, was also the year of least consumptive use.

---

[41] "Valley Consumptive Use," by E. B. Debler, *Transactions*, Am. Geophysical Union, Pt. II, National Research Council, 1937, Washington, D. C., pp. 532–536.

The effective heat in 1933 was approximately the same as in 1931 but consumptive use was 0.78 ft less. Lower temperatures in April, May, and June may account for a part of the lower use in 1933, with rainfall and other factors accounting for the remainder.

Land use is one of the most important factors causing variation in consumptive use. The cotton acreage in the Mesilla Valley declined between 1930 and 1935 and has increased since that time. Compensating changes were made in general crops or in the fallow acreage. The alfalfa acreage has remained practically constant for many years. The effect of differences in land use is most apparent in 1933, 1934, and 1935 (Table 4, No. (9)), when the government cotton-reduction program retired large areas not used for other crops. The difference of 0.73 ft in consumptive use for the years 1928 and 1935, years of nearly equal effective heat, is largely due to a reduction of 13,882 acres in irrigated area. It is possible, too, that water-surface evaporation and consumption by native vegetation growing along the Rio Grande was much less in 1935 than in 1928 as the runoff of the river at Leasburg, head of the valley, was only 69% as great as in 1928. The reduction in consumptive use in 1933 as compared with 1931 is explained in part by the fact that 6,870 acres were plowed under in 1933 and no other use made of the land that year. Nonproductive uses of water in these two years were probably about the same.

The low consumptive use in 1937 cannot be explained by any one of the factors mentioned. Unusually favorable circumstances must have prevailed in that year to account for the high crop yields and low consumptive use of water.

The corrected use data in Table 4, No. (9), have been corrected to a full-area basis by reducing the equivalent area by 50% of the area temporarily out of cultivation. This is based on an estimated consumptive use, by the land that is temporarily uncropped, of 50% of the cropped land. In 1927 development was incomplete; in 1933, 6,870 acres of cotton were plowed under but reported in crop; in 1934, 9,220 acres of cotton land were fallow but not reported; and, in other years, the corrected full irrigation development was set at 76,900 acres, which is the mean for the period 1928 to 1934, and the year 1937.

Wagon Wheel Gap Area, Colorado.—The area consists of a 222-acre watershed tributary to Rio Grande at Wagon Wheel Gap, Colo. Elevations range from 9,400 to 11,300 ft. The area is forested with Douglas fir and other growth typical of the central Rocky Mountains, but includes no agricultural land. Its water supply is limited to precipitation, which varies little from the average of 21 in. per yr. Runoff, and hence consumptive use, varies from year to year because of differences in intensity and occurrence of precipitation. There are no known seepage losses from the area. The data in Table 3, No. (10), are for watershed "*A*," used in the experiments of the Forest Service and Weather Bureau described by C. G. Bates and A. J. Henry.[42]

---

[42] "Forest and Streamflow Experiment at Wagon Wheel Gap, Colorado," by C. G. Bates and A. J. Henry, *Monthly Weather Review*, Supplement No. 17 (1922) and Supplement No. 30 (1928).

Black River, Wisconsin.—The drainage basin above Neillsville, Wis., comprises 770 sq miles of gently rolling land, 62% of which is cropped, 30% pastured, and the remainder wooded. The average elevation is about 1,200 ft. Temperatures vary from −40° to 101°, although summer temperatures are normally moderate. The growing season is 164 days. Annual precipitation averages only 31 in. but as a large percentage occurs in the growing season, and as winter precipitation is held in snow storage until spring, agriculture is successfully practiced without irrigation. During the period of runoff records, water shortage was severe in only one year. Consumptive use (Table 5, No. (11)) was obtained by deducting runoff from precipitation on the entire watershed.

Mad River, Ohio.—The watershed above Springfield, Ohio, covers an area of 480 sq miles of flat to rolling land with an average elevation of 1,100 ft lying about half way between the Ohio River and Lake Erie. About 33% of the area is cropped, 38% is pastured, and the remainder is woodland.

[a] U = Consumptive use, in ft; U_p = computed consumptive use; U_r = corrected consumptive use; and H = effective heat, in degree-days (F). [b] Dry year corrected by a quantity considered adequate to insure normal consumptive use. [c] Non-irrigable watersheds; Nos. (5) and (7) are irrigable.

Temperature extremes vary from −34° to 108°. The growing season is six months. Precipitation averages 38 in. per yr, of which about 21 in. occur in the growing season. This is adequate in all except a few short years for crop production. Consumptive use (Table 5, No. (12)) was obtained by deducting runoff from precipitation on the watershed.

Skunk River, Iowa.—The drainage area above Coppock, Iowa, is about 145 miles long and 20 miles wide and contains 2,890 sq miles of gently sloping prairie land, lying immediately east of Des Moines. The average elevation is about 700 ft. Crop land occupies 68% of the area, pasture 26%, and woodland 6%. Temperatures vary between extremes of −30° and 110°, and relative humidity is high. The growing season is about 205 days. Precipitation averages 32 in. per yr but has dropped as low as 18 in. Nearly two thirds of the annual precipitation falls in the spring and summer months, and the supply is ordinarily enough to mature crops. In a few recent years the supply has been inadequate. Consumptive use (Table 5, No. (13)) was obtained by deducting runoff from the precipitation falling on the entire watershed.

Sangamon River, Illinois.—The area comprises 2,560 sq miles of Sangamon River watershed above Springfield, Ill. It has an average elevation of 700 ft. The topography is gently rolling; 78% of the watershed is cropped, 18% is pastured, and the remainder is wooded. Temperatures vary from −24° to 107°, and the relative humidity is high. The growing season is about 220 days. Precipitation averages 36 in. per yr and is favorably distributed for crop use. A full water supply is obtained in nearly every year. Consumptive use (Table 5, No. (14)) was obtained by deducting runoff from precipitation over the entire watershed for the period 1921 to 1936.

North Fork of White River, Missouri.—The watershed above Tecumseh, Mo., comprises 1,180 sq miles of rough foothill country, with an average elevation of 1,200 ft, lying along the southern edge of the Ozark Plateau. There is a larger percentage of woodland than in any other area studied except the small Wagon Wheel Gap area. Only about 25% of the area is cropped and 28% pastured. Extremes of temperature vary from −29° to 106°. The growing season is about eight months. Precipitation, which furnishes the sole water supply, averages 42 in., of which 26 in. occurs during the spring and summer. The amount of precipitation fluctuates considerably but is seldom short.

[a] U = Consumptive use, in ft; U_p = computed consumptive use; U_r = corrected consumptive use; and H = effective heat, in degree-days (F). [b] Dry year corrected by a quantity considered adequate to insure normal consumptive use.

Consumptive use (Table 6, No. (15)) was computed for years of recorded runoff by deducting runoff from precipitation on the entire watershed.

Green River, Kentucky.—The watershed above Livermore, Ky., has an area of 7,800 sq miles, covering a large part of Kentucky and part of Tennessee, and is the largest area studied. The topography is rolling, with an average elevation of 600 ft. About 40% of the area is cropped, about the same percentage is pastured, and the remainder is wooded. Temperatures vary widely between winter and summer. The growing season is about eight months. Annual precipitation averages about 45 in., of which more than one half occurs in the growing season. This is normally sufficient for full crop requirements, although occasional shortages occur. Consumptive use (Table 4, No. (16)) was obtained by deducting runoff at Livermore from precipitation over the entire watershed in the period of runoff record, 1931 to 1936.

Tallapoosa River, Alabama-Georgia.—The Tallapoosa River above Wadley, Ala., drains an area of 1,660 sq miles ranging from an elevation of 1,200 ft at the southern end of the Blue Ridge Mountains in Georgia to 200 ft on the coastal plain of the Gulf of Mexico. The area is only 42% cropped, with 15% in pasture, the remainder being woodland. Temperatures have an extreme range of −8° to 103° but are normally moderate due to the proximity of the Gulf. The area is occasionally subjected to severe storms. The average annual precipitation is about 52 in., a considerable part of which occurs in winter. Spring and summer rainfall is usually adequate for crop requirements. Consumptive use (Table 5, No. (17)) was obtained by deducting runoff from precipitation on the entire watershed.

East Fork of Trinity River, Texas.—This area of 830 sq miles is upstream from the stream gage near Rockwall in northeastern Texas in the blackland prairie region, one of the richest agricultural sections of the state. The topography is relatively flat, ranging in elevation from 400 to 800 ft. Of the total area, 75% is in crops, 16% is in pasture, and 9% is woodland. The distance from the Gulf of Mexico is sufficient so that temperature variations are wide. The growing season is from April to October. Precipitation furnishes the entire water supply but in many years is inadequate. It averages 21.6 in. in the spring and summer months. Runoff is flashy and dependent on storm rainfall. Consumptive use (Table 6, No. (18)) was determined by deducting runoff from precipitation on the entire watershed.

Cypress Creek, Texas.—The drainage area, containing 848 sq miles upstream from the gaging station at Jefferson, is in eastern Texas. The elevation ranges from 200 to 400 ft and the topography is gently rolling. The area was once heavily timbered but is now (1941) about 50% cropped and 20% pasture. Soils vary from sandy to tight clay. A wide variety of crops, including much truck and fruit, is grown. Temperatures vary widely from below zero to 110°. The growing season is about 280 days. Precipitation, the sole source of water supply, averages 43.9 in. per yr, of which about 70% occurs in the growing season and, except in dry years, is adequate for crop production. Relative humidity is high. Consumptive use (Table 6, No. (19)) was determined by deducting runoff from precipitation on the entire watershed.

San Jacinto River, Texas.—The San Jacinto River Valley is a flat sandy area of 1,811 sq miles, varying from 50 to 400 ft in elevation, on the coastal plain of the Gulf of Mexico a few miles north of Houston, Tex. Of the total area, 29% is pine forest, 38% prairie, and 33% cultivated. The climate is mild and humid. The precipitation is adequate for crop requirements in most years, but is frequently so intense that high runoff and shortages of moisture occur. Consumptive use (Table 6, No. (20)) was estimated as the difference between precipitation and measured outflow. Ground-water movement out of the basin was considered negligible.

Greenfields Division, Sun River Project, Montana.—The area consists of benchlands lying between Sun River and Muddy Creek near Great Falls, Mont., and draining into Muddy Creek. Elevations range from 3,600 to 4,000 ft (see No. 9*a*, Table 1). The topsoils are underlain with terrace gravels over shales so that excess waters are readily drained away. There is negligible runoff from non-irrigated lands tributary to Muddy Creek except in the case of unusual flood conditions. The acreage irrigated in 1937 and 1938 was 34,250. With allowance for 1,000 acres of seeped land and for right of ways and farmsteads, the area equivalent in use to irrigated land is estimated at 37,500 acres. Temperatures range from −46° to 112°. The growing season, based on smoothed minimum temperatures, is about 180 days. An adequate water supply is furnished through the Greenfields Canal from Sun River and from storage in Pishkun and Gibson reservoirs. Alfalfa and small grains are the main crops, although some sugar beets and seed peas are also grown. Ground-water levels at the beginning and end of the year are believed to be essentially the same. The following consumptive-use data were furnished by the Sun River Project office:

Year	Consumptive use (ft)	Effective heat (degree-days, F)
1937	2.02	7,800
1938	1.95	6,670
Mean	1.98	7,240

Pecos River Area near Carlsbad, N. Mex.—This area includes the lands of the Carlsbad Reclamation Project plus adjacent lands east of the Pecos River, all of which are supplied with irrigation water from the Pecos River. The average elevation of the area is approximately 3,100 ft (see No. 9*b*, Table 1). The irrigated soils are fairly tight, but adequate drainage removes any excess water. During the period covered by this study the acreage irrigated has remained about constant. Allowing for water-using areas in addition to those lands actually irrigated, the total water-using area has averaged 37,850 acres, which has been adopted as the equivalent area. Temperatures range from −17° to 112°. The growing season averages about 240 days. An adequate water supply is provided from the Pecos River, which is more or less controlled by storage reservoirs upstream. The main crop for a number of years has been cotton, but a large acreage is also devoted to alfalfa. Ground-water levels were assumed the same at the beginning and end of the period, although variations in the depth to the water table undoubtedly explain some of the wide variations in computed consumptive use for individual years.

Consumptive-use data comparable with Tables 2 to 6, inclusive, for the Pecos River area, are as follows:

Year	Consumptive use (ft)	Effective heat (degree-days, F)
1921	2.38	12,400
1922	2.68	13,000
1923	2.66	12,600
1924	2.74	12,450
1925	2.53	13,640
1926	4.50	12,850
1927	2.60	13,870
1928	2.54	13,740
1929	4.02	13,190
1930	3.54	14,620
1931	2.96	14,110
1932	2.92	13,050
1933	2.83	15,290
1934	2.21	14,700
1935	2.29	14,680
1936	3.25	13,750
1937	3.74	12,640
1938	2.61	14,420
Mean	2.94	13,600

Of the total consumptive-use average of 2.94 ft, 0.94 ft is supplied by precipitation, leaving 2.00 ft to be supplied by irrigation water. The data used consist of runoff records from the New Mexico State Engineer and the Geological Survey with other information furnished by the Carlsbad Project office.

DISCUSSION

E. B. Debler,[43] M. Am. Soc. C. E.—In regard to the orchard areas discussed by the authors, the writer made some study of the Kings River area in California, which is probably the most typical upon which information is available in that region. There seems to be no material departure from the curve of Fig. 2. In other words, crops are a corollary to the number of thousands of heat units. They go with that factor, and, although the authors state that the consumptive use in orchards is low, the writer believes that, in areas where cover crops are maintained to produce fertility, consumptive use will lie on this general graph (Fig. 2). The areas that are getting along with a lower consumptive use are, as a rule, the so-called clean cultivated orchards, and agriculturists now agree that such a condition can be only more or less temporary, and that with the maintenance of fertility those areas, in time, must go to cover crops.

It may appear rather extraordinary that so few areas were selected in what might be called the more highly developed, long-irrigated regions, such as the South Platte and Arkansas River areas in Colorado, and others. The situation is that, almost without exception, the older irrigated sections are subject to chronic shortages of water. The writer doubts very much that the irrigated area of the South Platte River Basin enjoys a water supply that (on the average) is more than two thirds of a full supply. Two difficulties were encountered in that area:

(1) The situation presents an almost insurmountable condition for the correction of data to represent consumptive use with a full supply, as records on water deliveries are lacking; and

(2) Reliable records on irrigated areas are not available, a situation that could not be overcome without considerable expense.

The available information was limited to reports of the water commissioners, and there are too many of those reports made with an eye to future water-rights adjudication suits! For these reasons, in areas where water is most valuable and where there is a fight for water from year to year, engineers are handicapped in arriving at consumptive use.

As to the possibility of using annual temperatures: The classic example encountered by the writer is a comparison between the Klamath Project in Oregon and a project in eastern Montana. They have about the same annual temperature. The Klamath Project has an average temperature even higher than the one in eastern Montana; yet it is subject to frost in every month of the year. Naturally, its consumptive use is very much less than that of the eastern Montana Project, where the temperatures are extremely low in the winter, but the summer temperatures are as high as they are in Texas.

In other words, what the engineers were attempting to arrive at was a correlation applicable in every location rather than an easier correlation that might not have general correlation for the United States as a whole. The

---

[43] Hydr. Engr., U. S. Bureau of Reclamation, Denver, Colo.

Klamath Project will show a frost-free period on an average of less than 100 days. The project in Montana will show a frost-free period of 150 days. The results just are not comparable. Notwithstanding this difference in the records, the Klamath area grows plenty of potatoes, which cannot be done in some areas showing a much higher average temperature. The writer is only hopeful that more information can be developed. He found an extreme dearth of records, faulty in many particulars—most commonly with reference to the irrigated areas. In some areas the consumptive use is so small in proportion to the inflowing and outflowing waters that no one can be sure of results, as a very minor error in stream flow may equal the entire consumptive use!

RHODES E. RULE,[44] ASSOC. M. AM. SOC. C. E. (by letter).—For many years it has been known to irrigation engineers who have investigated the subject that a close correlation exists between maximum temperatures and consumptive use. The authors' paper is refreshingly practical in its application of this relationship. Too often the results of extensive research are submitted in involved and inconclusive treatises beyond the grasp of the average engineer who has neither the time nor equipment to attempt to translate them into terms of useful application.

Determination of valley consumptive use lends itself to several methods of approach. By pursuing these courses separately and then reconciling the results as the final step it is possible to arrive at a conclusion with a probable error not larger than required by the uses to which the data may be put. The authors have added another avenue of attack which is simple and apparently effective, subject to certain limitations.

The following discussion relates to specific details taken in the order of their presentation in the paper and concludes with data for two Southern California basins which, as will be shown, do not accord with the empirical relationship developed by the authors.

Definitions.—Omission of the term "nonrecoverable deep percolation loss" from the definition of valley consumptive use clears up an inconsistency. This term should never have been introduced by the Committee on Duty of Water[3] since, as the authors correctly state, it "is a form of outflow independent of the factors influencing transpiration and evaporation."

A confusion of terms exists here. "Deep penetration," "deep percolation," or simply "penetration" and "percolation" have been used variously to designate that part of the moisture reaching the earth's surface which passes downward to below the root zone. As such it is not lost to available water supply and is certainly not consumptive use. Under ordinary conditions it ultimately reaches the permanent water table and becomes available for recovery by pumping or for use where it reappears at the surface as effluent seepage. In all but a few exceptional cases this availability for use is within the valley where the deep penetration originally occurred and there is no net loss of supply to the valley. On the other hand, if "nonrecoverable deep percolation" is taken to mean ground water which escapes the valley through deep subterranean channels or simply as underflow at the lower end of the area it should be included in "valley outflow" even though its estimation be a mere guess. Certainly if its quantity is large in a particular case it becomes an important item for investigation and estimate. If carelessly lumped in with consumptive use the latter would be too high and the results misleading.

---

[44] Cons. Eng. Geologist, Burbank, Calif.

Lest the foregoing be thought to be mere quibbling over terms of no particular consequence it should be realized that, in spite of its basic simplicity, knowledge of consumptive use has been hampered by lack of agreement and confusion over definitions and, perhaps, a misunderstanding of the physics and geology of subsurface waters. Involving nothing more complicated mathematically than simple arithmetic the inventory of valley-water supplies is one subject concerning which there should be little disagreement as to methods and definitions.

Field-Plot Experiments.—In the discussion of plot experiments the authors have failed to recognize the valuable and determinative work done by H. F. Blaney, M. Am. Soc. C. E., F. J. Veihmeyer, Colin A. Taylor, Assoc. M. Am. Soc. C. E., and others. The thought seems to persist that plot experiments have failed to account for deep percolation and surface losses. This was the conclusion of the Committee on Duty of Water,[3] and was unquestionably true of the earlier investigations; but there are now at hand the results of much definitive work in which these losses have been measured or can be calculated from the experimental data. Some of these data are reported in papers referred to by the authors.[9, 10] The principal deficiency is in variety of crops and climatic conditions. Much of the available information relates to tree crops in California.

By proper use of the field-plot method consumptive use can be measured under actual field conditions with remarkably small error. Essential to success is careful selection of a location having uniform soil and representative crop conditions. Having such a location the soil moisture is determined by sampling before and after measured applications of irrigation or rain water. Sampling is extended to below the root zone. Surface runoff can be trapped and measured or kept to a negligible quantity by suitable control. Evaporation and transpiration are readily computed from the decrease in measured soil moisture between applications of water. Plotted foot by foot, the consumptive use follows smooth curves which permit ready detection and evaluation of deep percolation since any excess of applied water over that accounted for by these curves, plus runoff, may be ascribed with certainty to deep percolation. By careful application of water to suit the crop demands, deep percolation may be practically eliminated. The only qualifying conditions are that the water table must be beyond the reach of plant roots, the soil should be uniform, and the crop representative.

There is no surer method for the determination of consumptive use by individual crops or measurement of evaporation from bare soils than by the use of field plots if suitable locations are available and the work carefully done. It is admittedly expensive but the results justify the cost.

Integration Method.—The authors state that the integration method used by Mr. Blaney depends upon tank experiments. This is only partly true. Long-continued and successful use of the field-plot method provides the background for estimating many of the unit values in the integration method as applied by Mr. Blaney and his associates. Tank experiments become necessary where a high water table exists and the field-plot method cannot be applied.

In the last analysis the integration method relies on the judgment of the person applying it. If this judgment is to be good it must be based on a thorough knowledge of the experimental field including field-plot, tank experiments and all other sources of information.

Quantitative values of annual consumptive use by individual crops are known to cover a wide range. Under fixed climatic conditions consumptive use varies directly with total leaf surface and, with annual crops, the length of the actual growing period. Double cropping results essentially in a doubled consumptive use on an equal area. The data of Fig. 2 must be recognized as being based on a variety of vegetative types and farming practices which, when averaged, produce a high correlation between consumptive use and effective heat as defined by the authors. The same degree of correlation would not exist as between different crops. Grape vines consume far less water per acre than mature citrus trees or alfalfa. This is reasonable from a consideration of the relative leaf surfaces. A valley in which vineyards predominate doubtless would produce a point which would fall well below the curve shown. It follows that successful use of the authors' method in estimating valley consumptive use must be predicated upon a variety of conditions which, in the aggregate, produce "average" results. Specialty crops require special attention and analysis.

Knowledge of consumptive use will be served best by concerting research effort toward accurate determination of use by the more common crops under true field conditions and the relation of the resulting experimental data by some such common denominator as effective heat in order that reasonable estimates may be made for regions where experiments have not been undertaken. It is probable that comparison on the basis of relative pan evaporation would be more satisfactory but temperature records are available nearly everywhere and the effective heat method has a correspondingly wider field of utility.

All this discussion sums up to the writer's opinion that the integration method, based on reliable experimental data and checked by an inflow-outflow computation, provides the best method for estimating existing consumptive use.

The effective heat method appears to offer real promise in two ways:

(1) As a basis for comparison in estimating unit values of consumptive use for regions where experimental data are lacking (these would then be most useful of application in the integration method); and

(2) In estimating average consumptive use for proposed projects where temperature records alone are available and where a preliminary value will suffice.

Effective Heat.—Selection of 32° F as a base for computation of effective heat is subject to question and further analysis. A rigorous study of the subject belongs in the province of pure science and involves many variables. It is doubtful if a better solution could be obtained than by further investigation along empirical lines.

A glance at Fig. 1 suffices to show that, for the particular data from which this block diagram was prepared, mean maximum temperatures above, say, 52° F would produce a better monthly correlation with consumptive use and, roughly, each 10° above 52° would result in monthly consumptive use of 0.1 ft in depth.

The authors state that comparative studies were made on other bases before 32° was selected. Nevertheless, lacking definite evidence to the contrary, the writer inclines to the belief that a somewhat higher base would be more satisfactory.

Length of Growing Season.—The authors' method of calculating the length of growing season is tedious and the results do not appear to warrant the work involved. Further, since it is arbitrary, it fails to take account of farming practice which varies from place to place. Where full information regarding such practice is available or can be readily obtained in the field it offers a much better basis for computation.

Failure of the method is most clearly shown in Southern California for which no data have been given in the paper. For all practical purposes the use of twice-repeated five-day moving averages results in a 365 day growing season for the coastal plain and interior valleys of Southern California. It is obvious that some other criterion must be adopted for this location.

Careful attention to cultural practices will provide the basis for estimating an average growing season for any given area.

In many parts of California annual row crops are planted during March and April and require from 90 to 120 days to mature. After the spring crop is harvested some of the acreage is replanted. On the average, taking double-cropping into consideration, the "growing season" for row crops probably does not exceed 150 days. Following harvest some farmers practice weed control by cultivation; others permit weeds to flourish and later plow them under for green manure. Clearly variations in consumptive use by such crops are dictated more by individual cultural practice than by any arbitrarily defined growing season.

Similarly, tree crops will have widely varying uses depending upon practice with respect to cover crops now being used to an increasing extent by California farmers. Deciduous trees without a cover crop will have a growing season of perhaps 250 days, whereas a cover crop would result in appreciable consumption during every month of the year.

In other words the length of the season during which plants will grow is not controlling unless there are growing plants to utilize the available heat during this season.

The authors have based their studies on the assumption of an adequate water supply. Perhaps this should be further qualified by the assumption of an "adequate plant supply." As pointed out this is not always true, particularly where the frost-free period is long. It is concluded that cultural practice is more important than an inflexible definition of growing season based on minimum temperatures.

Annual Variations in Consumptive Use.—Annual variations in calculated consumptive use by the inflow-outflow method are usually such as to discourage reliance on one-year computations. To the causes mentioned by the authors should be added the impossibility of evaluating, accurately, water in transit to the water table. Where the preceding year has been exceptionally wet and the depth to the water table is large (in Southern California it may be several hundred feet) the quantity of water in transit may be sufficient to result in gross errors in calculated use during a single year. Experiments by the writer demonstrate that a number of years may elapse before influent seepage at the valley margin reaches the main ground-water body by lateral percolation. Vertical seepage to the water table is not usually so delayed but may require a year or more in older alluvium.

As distinguished from these apparent but not true variations there also must be considered the normal variation resulting from rainfall differences. The authors have corrected for dry years by adding a quantity considered adequate to insure "normal consumptive use." Presumably the object was to arrive at a set of figures of consumptive use based on a full evaporation opportunity. The difficulty here lies in the fact that heavy rainfall encourages, and scanty rainfall discourages, all types of vegetative growth, including a variety of weeds and grasses which are heavy consumers of water. This variation in use is independent of effective heat. The net effect is the same as if the equivalent area were increased during wet years and decreased during dry years. "Normal consumptive use" is not a constant but an average. If an addition is made for dry years a subtraction would be equally in order for wet years.

Data for San Jacinto Valley, California.—Studies[45] by Mr. Blaney, A. A. Young, Assoc. M. Am. Soc. C. E., and Paul A. Ewing, reported in 1941, provide the basis for the following analysis of an interior valley in Southern California.

The San Jacinto Basin comprises 162,100 acres, of which (1939) 31,500 are irrigated, 95,500 dry farmed, 28,200 in native vegetation, and 6,900 miscellaneous (water surfaces, towns, etc.).

Irrigated crops of the basin consist of some 10,000 acres of irrigated trees, both citrus and deciduous; 6,000 acres of alfalfa; 12,000 acres of row crops; and 2,500 acres of miscellaneous crops including grain; 1,000 acres were classed as prepared land—idle.

Consumptive use for an 18-yr period, 1922 to 1939, was computed at 198,500 acre-ft by the inflow-outflow method, and for 1938–1939 was estimated as 204,200 acre-ft by the integration method. Consumptive use on irrigated lands approximates 2.3 ft.

The writer has estimated the equivalent area at 90,000 acres with a consumptive use of 2.25 ft.

---

[45] "Utilization of the Waters of Beaumont Plains and San Jacinto Basin, California," Progress Report, U. S. Dept. of Agriculture, SCS, 1941.

Mean maximum temperatures are not published for any station in San Jacinto Basin but records are available for two nearby stations having similar climatic conditions and less than a degree difference in mean temperature.

Applying the authors' moving average scheme for determination of the growing season it was found that for all practical purposes the entire year would be so classified. Since it was apparent that this was not in accord with the facts a different method was adopted.

Based on cultural practice as observed in the field the "growing season" ranges from a minimum of about 150 days for row crops to a maximum of 300 days for trees. By an approximate system of weighting according to acreage a mean growing season of 214 days was estimated. In general this covers the period from April through October and coincides with the irrigation season for this location.

Computed average effective heat during the 18-yr period, for the average year and for a 214-day season (April 1 to October 31), was as follows:

Length of season (days)	Day-degrees
365	17,700
214	11,900

Plotted in Fig. 2, on the basis of 11,900 day-degrees and a consumptive use of 2.25 ft, it is seen that the point falls below the defined curve. In terms of consumptive use it falls 0.4 ft short of the amount indicated by the curve, even after adjusting the growing season as explained herein.

Three apparent reasons come to mind to explain the discrepancy. First is the difficulty and expense of water development from which has grown a frugal system of irrigation practices. Much of the supply is pumped by individual farmers or sold on a unit basis, both conducive of careful husbanding of irrigation water. Second, the average crop grown may consume less water than the average in the valleys studied by the authors. Third, throughout most of the basin the water table lies well below the root zone, thus limiting consumptive use to water applied to the surface, either artificially or naturally.

Data for San Gabriel Valley, California.—Mr. Conkling made extensive investigations in the San Gabriel Valley,[46] in the intermediate climatic zone of the South Coastal region of Southern California. Of 133,000 acres in the basin, 85,000 were irrigated in 1926; 33,000 were fallow, and 15,000 classed as waste. The equivalent area, as estimated by the writer, was 103,000 acres. Consumptive use from inflow-outflow computations from 1923–1924 to 1926–1927 averaged 188,000 acre-ft. By integration the use was estimated to be 195,000 acre-ft or 1.9 ft in depth on the equivalent area.

Temperature records are published for the City of Pasadena, Calif., at the westerly edge of the basin. The mean effective heat for three seasons, 1924–1926, was 10,600 day-degrees for a growing season from April 1 to October 31.

Plotted in Fig. 2 the point for San Gabriel Valley falls below the curve, consumptive use being 0.6 ft less than would be inferred from the effective heat. As in the San Jacinto Valley this is in spite of a materially shorter growing season than would have resulted from using the authors' method of determination.

---

[46] "San Gabriel Investigation—Analysis and Conclusions," by Harold Conkling, Report, Div. of Water Rights, Dept. of Public Works, State of California. 1929.

Conclusions.—The situation in Southern California is such that modifications of the proposed method must be made before it will yield satisfactory results. As has been shown the growing season must be ascertained by reference to agricultural practice and field observation of the growth habits of the local plant life.

Also, the water supply situation must be considered. Shortage of supply is the rule if viewed in relation to regions such as have been studied by the authors. This does not necessarily imply an actual shortage of water required to produce commercial crops. More nearly the truth is that scarcity and high cost of water have promoted a careful conservation of all available water so that a portion of what would be normal consumptive use in other parts of the country has been salvaged by cultural methods aimed toward the highest possible duty of water.

It is possible, also, that crop types prevailing in Southern California are such as to have a lower average use than in the regions represented by the curve in the paper.

Finally, and perhaps most important of all, is the situation regarding evaporation opportunity by reason of the ground-water level. Apparent from a reading of the area descriptions in the Appendix is the fact that the study areas chosen by the authors are nearly all regions of high ground water. This is emphasized by the repeated references to artificial drains. Under such conditions the evaporation opportunity is high regardless of whether land is in crop or not. This being the case there exists a near maximum utilization of available heat in evapo-transpiration processes. There is little opportunity to conserve moisture during the period when lands are not in crop. On the contrary, an attempt at such conservation might well result in concentrating alkali near the ground surface to the detriment of the lands.

Contrasted with these conditions an entirely different situation exists where depth to ground water is considerably in excess of the depth of the root zone. Here transpiration may be practically stopped during the period between crops, and evaporation is limited to losses following precipitation. Available water supply thus may be utilized more efficiently. Identical crops may be grown with a materially lower consumptive use without affecting yields or depriving plants of water which they are capable of using beneficially.

In this connection it should not go without mention that because of high ground water under cropped lands an enormous quantity of water is unnecessarily consumed each year while on the same stream systems there exist severe downstream shortages. From the comparisons given herein this excess consumption may be in the order of 0.5 ft in depth each year. This constitutes a potential water supply of significant quantity in many regions. Available supply is never exhausted until the water table is kept at sufficient depth below the surface to preclude such losses. In many cases drainage by pumping or substitution of a pumped supply for a portion of the gravity supply would result in benefits such as alkali and weed control which may compensate in large measure for increased costs.

From these general considerations, substantiated in a measure by the data cited herein, it is suggested that in the application of the authors' method to a particular location careful consideration must be given and proper correction made for differences in consumptive use which may arise from: (*a*) Irrigation practice, (*b*) crop types, and (*c*) depth to ground water.

In closing the writer wishes to express again his appreciation of the value and practicability of the authors' work. If most of this discussion has been critical let it be added that it is intended to be constructive. Mere confirmatory discussion is usually little more than sterile.

EDGAR E. FOSTER,[47] ASSOC. M. AM. SOC. C. E.—The consumptive use of water for agricultural purposes provides one of the crucial problems of irrigation engineering, and the authors are to be commended for searching for some logical basis for solution. It is evident that they have made a careful study of the subject.

Since water used in irrigation is consumed chiefly in evaporation and transpiration, it may be reasonably expected that there should be some relationship between heat and the consumptive use of water; yet the graph, Fig. 2(*a*), shows such a remarkably close correlation (in contrast with the authors' statement that a rather wide variation exists in plotting individual years as shown by Fig. 2(*b*)) that it appeared to the writer that the data should be tested for correlation by the methods of statistics.

TABLE 7.—CORRELATION COEFFICIENT FOR WAGON WHEEL GAP

The coefficients of correlation between the water used, in acre-feet, and the effective heat, in day-degrees, were calculated for ten stations with records ranging from thirteen to sixteen years, the data for which are given in the Appendix. These coefficients were computed by the formula,[48]

$$r = \frac{X\,Y}{\sqrt{\Sigma X^2 \,\Sigma Y^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

---

[47] Head, Flood Control Section, U. S. Engr. Office, Omaha, Nebr.

[48] "Handbook of Mathematical Statistics," by H. L. Reitz, Houghton Mifflin Co., 1924.

in which: r = the correlation coefficient; X = the deviation from the mean water used for the individual stations; and Y = the deviation from the mean effective heat for the individual stations.

The method of computation is given in Table 7, which contains the entire work of the calculation of the correlation coefficient for the valley of Wagon Wheel Gap. Substituting the appropriate values from this table in Eq. 1, $r = +0.265$, with a probable error, e, of $e = \dfrac{0.6745\,[1 - (0.265)^2]}{\sqrt{14}} = 0.168$.

The characters, U_r and H, have the same significance as in Table 3, Valley (10). It will be noted that the corrected values of the consumptive water are used as given by the authors. In general, the corrected data would give better correlation than the uncorrected values, but because the object is to determine how much water could be used, rather than how much had been used, the corrected values are justifiable.

TABLE 8.—SUMMARY OF THE CORRELATION COEFFICIENT r AND THE PROBABLE ERROR e

The computed correlation coefficients of the ten basins, together with their probable errors, are given in Table 8.

As is shown in the theory of statistics, the value of the correlation coefficients varies from − 1.0 for an inverse mathematical relationship, through values approximating 0.0 for purely chance, to 1.0 for a direct mathematical relationship. From Table 8 it will be seen that the correlation coefficients between consumptive water used and the effective heat as defined and calculated by the authors vary from − 0.254 to + 0.282 with a mean of 0.012. There are five positive values and five negative values. The probable errors of the coefficients, being dependent upon the number of observations as well as upon the magnitude of the deviations, are large (in some cases several times as large as the coefficients themselves), but in no case will the combined coefficient and probable error be great enough to show significant correlation. The low values of the coefficients, the diversity of the signs, and the relatively large probable errors show conclusively that there is no correlation between consumptive water and the effective heat for the individual years.

Nine of the ten valleys in Table 8 are not in regions where irrigation is practised. From this it may be inferred reasonably that the correlation is not caused by inaccuracies in estimating the area equivalent in rate of use to the cropped area, or changes in crop distribution or crop damage, but may be attributed to the lack of correlation in the various hydrological data.

The correlation coefficient was not computed for the averages of the effective heat and water in Table 1 because the data are not entirely comparable on account of the variable number of years of record. A high degree of correlation is plainly evident between the average water used and the effective heat as shown by Fig. 2(*a*), and a computed coefficient would probably have little added significance.

There now arises the question of what is the reason for the high correlation between the means as shown by Fig. 2(*a*), whereas there is no correlation between the water used and the effective heat for the individual years. A part of the improved correlation is probably obtained by averaging the inaccuracies noted by the authors. These sources of error are: Inaccurate records of discharge; inaccurate estimates of ground water; inadequate precipitation and temperature records; variability in the climatic elements; inaccurate estimates of the water used; and changes in crop distribution and reduction in the water demand because of crop damage. Since all these factors operate each year to a varying degree, it is likely that the variations caused by these factors offset each other to a considerable extent. However, there will very likely still be deviations that will be reduced further by averaging a series of data of successive years.

Nevertheless, in addition to the valid averaging of deviations, a kind of spurious correlation is obtained in the averages of water used and effective heat, which is the result of dividing the individual yearly values by the same factor—in this case, the number of years of record. This false or exaggerated type of correlation is pointed out by various writers of mathematical statistics.[49,50] Improvement in the correlation between two variables is caused by operating on the concurrent data in a series of observed values with a common divisor. It is not possible to estimate how much apparent improvement in the correlation may be due to this cause but it may be considerable. The uncertainty is enough to vitiate the results observed in Fig. 2.

In view of the lack of correlation for individual years, it is evident that the method proposed could not be used to estimate the year-to-year requirement of consumptive water with any degree of certainty since, for any given value of annual heat, it would be a matter of chance whether or not the computed depth of water would be sufficient for that year. The use of Fig. 2(*a*) would provide a somewhat more reliable value for the average annual consumptive water but, because of the spurious correlation obtained by the use of averages as data, the reliability of the value would not be great.

It is hoped that the authors will continue their search for means of estimating the quantity of consumptive water used in agriculture. A method utilizing more than one climatic element would probably be more successful. However, a high degree of correlation cannot be expected, although a coefficient should be higher than 0.50.

Charles H. Lee,[51] M. Am. Soc. C. E.—This important subject has been presented in an analytical manner from limited, although widely distributed, data, and the authors have developed a simple method of computing con-

sumptive use of water that is very promising. From this as a base, they point out that it is an easy step to determine water requirements for crops and from thence to farm delivery and diversion requirements, all of which are essential data for the design of an irrigation project. They are to be commended for the broad view they have taken of the problem and their recognition that many of the earlier studies were of limited scope or objective, had differing concepts of the meaning of consumptive use, and hence have little value in a generalized study. An example of this fact was the frequent use of stream flow depletion as a measure of valley consumptive use. In 1930 the writer pointed this out in commenting upon the Report of the Duty of Water Committee of the Irrigation Division on consumptive use of water in irrigation.[52] At that time he suggested the adoption of the climatic instead of the crop year and the topographic or geologic unit of area instead of the project area. It is noted that the authors have proceeded in accord with these ideas.

The authors state that their basic data of consumptive use have been obtained from stabilized irrigation areas in which general crops are grown and which have adequate water supply and full project development. An added condition has been absence of nonrecoverable loss by deep percolation. These conditions should be considered and, if necessary, adjusted in applying their results to other areas.

The authors have developed a master curve for consumptive use (Fig. 2), well supported by plotted points, which they state (see heading "Valley Areas Studied") "represent practically the entire range of growing conditions and types of agriculture found in the United States." This statement is believed to be rather broad and to overlook entirely the Southwest, the Pacific Coast and other areas where growing conditions and types of irrigated agriculture differ widely from those in the cold mountain valleys that make up most of the irrigated areas selected for study. From the standpoint of production and economic importance, the omitted areas are of greater importance than are those for which representative valleys have been included. The master curve, therefore, should be accepted conditionally and should be considered as applicable only to the Rocky Mountain and humid sections of the United States until proved to have wider scope.

In order to define more clearly the limitations of the master curve, Table 9 has been compiled from data in the Appendix, and gives both average annual precipitation and that during the growing season, the length of growing season, and vegetation. It appears that, in most of the selected valleys, 50% or more of the precipitation falls within the growing season. In contrast to this, in the Southwest, and particularly on the Pacific Coast, practically no precipitation falls within the growing season.

It is further apparent that the principal irrigated crops are limited to alfalfa, native hay, grain, potatoes, and cotton, omitting entirely all the extensive orchard, vineyard, field, and vegetable crops raised in the Southwest and on the Pacific Coast, as well as rice, lettuce, cantaloupes, celery, artichokes, beans, seeds, and many other specialty crops of which large acreages are irrigated. With respect to the length of the growing season, the only irrigated area considered by the authors exceeding 165 days is Mesilla Valley, whereas in most of the irrigated sections of the Southwest and Pacific Coast the growing season exceeds 225 days and in some favored localities 300 days. In addition to differences in crops in the two regions, there are also vast differences in the methods of handling water and in the economics practised in its distribution and application. Some of these differences may well have sufficient influence upon consumptive use to overshadow that of effective heat.

The writer regards the element of precipitation as one most likely to cause confusion and error in the use of the master curve. The mean consumptive-use values that support the curve have apparently been built up with the inclusion of total annual precipitation (see heading "Method of Study: Measurement of Use of Water"). This varies for the selected valleys from 7 in. to 10 in. (with one instance of 17 in.) and 50% or more falls within the growing season (see Table 9). Considering irrigated areas throughout the West, precipitation varies from 3 in. to more than 20 in. and on the Pacific slope occurs mostly during the winter season. Precipitation is ordinarily disposed of by: (1) Interception; (2) immediate evaporation from the soil; (3) runoff; (4)

temporary absorption as soil moisture, returning to the atmosphere later as soil evaporation and transpiration; and (5) deep percolation passing beyond the reach of plant roots and ultimately becoming ground water. The relative distribution of total precipitation among these fractional elements varies greatly, depending upon the season of the year, the frequency of storms, the intensity of precipitation, the type of vegetation, the slope of the ground surface, the character and condition of the soil, etc. With precipitation corresponding to that in the valleys selected by the authors, the deduction of 7 in. to 10 in. in compiling water requirements from the master curve would probably not involve appreciable error; but an attempt to apply this assumption in valleys where the precipitation exceeds 10 in., and occurs during the winter, is likely to cause a very serious error. For this reason, the writer suggests that the master curve be supported by consumptive-use values that include only soil moisture at the beginning of the growing season (or precipitation during the growing season, whichever is more appropriate), rather than total precipitation, thus omitting the features that are foreign to consumptive use. Established methods are now available for measuring available soil moisture within the root zone at the beginning of the irrigation season so that this quantity is no longer indeterminate.[53] Its use in areas with little or no precipitation during the growing season, and the use of precipitation during the growing season in other areas, for the purpose of determining consumptive use, is far more logical than the use of total precipitation. Conversely, when computing water requirement from the master curve, either soil moisture at the beginning of the growing season or precipitation during it should be deducted.

The writer is in agreement with the authors that with present improvements in method and equipment many of the uncertainties of tank data have been eliminated. Careful consideration must still be given to the matter of exposure, however, to insure dependable results from tank observations.

The authors refer to the close correlation between transpiration and meteorological phenomena, listing especially evaporation from water surface, air temperatures, solar radiation, and wet-bulb depression readings. The evaporation from water surface probably represents the integrated effect of all the other factors mentioned. As an illustration of this fact, the writer prepared a graph on which were plotted the transpiration ratio and evaporation from water surface for alfalfa during the growing season as measured in tanks by Messrs. Briggs and Shantz at Akron, Colo., from 1911 to 1917,[54] and by A. C. Dillman at Newell, S. Dak., from 1912 to 1918, and at Mandan, N. Dak., from 1919 to 1922.[55] The observations were made in sunken land pans, 8 ft in diameter, reduced to reservoir surface by the use of a coefficient of 0.94. Although it shows a considerable spread among plotted points, Fig. 3 indicates a definite trend in the form of a straight-line relation.

[55] "The Water Requirements of Certain Crop Plants and Weeds in Northern Great Plains," by A. C. Dillman, *loc. cit.*, Vol. 42, 1931, pp. 187–238.

The authors state (see heading "Influence of Meteorological Factors") that "Although solar radiation gives one of the best correlations with transpiration and evaporation, growing-season temperatures more nearly parallel the cycle of plant growth." The latter statement is not confirmed by the work of R. F. Goudey, M. Am. Soc. C. E., at Los Angeles, Calif. He found that the growth of algae in reservoirs follows the ultraviolet component of solar radiation more closely than it does temperature.[56] The writer believes that there is much yet to be discovered through correlation of evaporation and transpiration with the components of solar energy, and especially with the ultraviolet radiation.

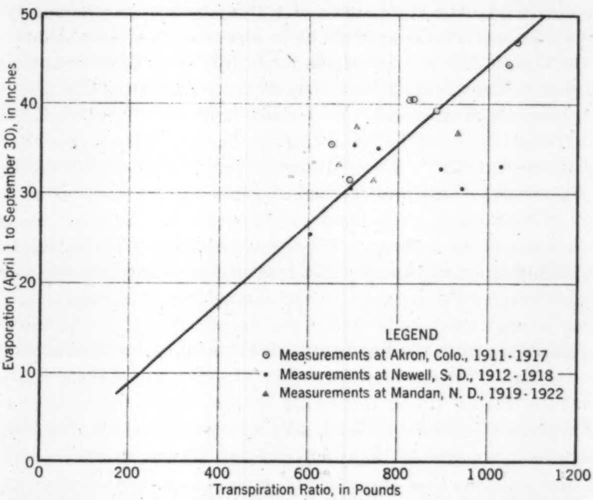

FIG. 3.—RELATION OF EVAPORATION FROM RESERVOIR SURFACE AND TRANSPIRATION RATIO FOR ALFALFA

An especially interesting feature of the authors' paper is the correlation of consumptive-use and watershed losses. Water loss from large land areas in the United States has been the subject of engineering study by two specialized groups—irrigation engineers working in the plains and valleys of the semi-arid and arid West, and water supply engineers working in the humid East and the mountain watersheds of the West. The former have adopted the term "consumptive use of water" to represent the losses in irrigated agriculture by transpiration and soil evaporation. To represent the loss from watersheds by transpiration, soil evaporation, and interception, the latter have used various terms, such as evaporation, evaporation from land areas, evapo-transpiration, total loss, water losses, fly-off, and total evaporation, of which the latter has received much recent use.[57] (The term "total evaporation" has been adopted by the writer as the most expressive short term in current use.)

[57] "Hydrology of the Physics of the Earth," National Research Council (see chapter on "Transpiration and Total Evaporation," by Charles H. Lee).

Although the factors of interception and soil evaporation are of greater importance in total evaporation than in consumptive use, yet otherwise the two quantities (total evaporation and consumptive use) have similarity in that losses under both normally occur with conditions of ample water supply. This fact gives validity to the comparison of water losses from adequately watered irrigated valleys and humid watersheds as attempted by the authors.

The selection of humid watersheds made by the authors is not duplicated in the literature and suggests that they have not followed the line of recent technical papers, beginning with W. G. Hoyt, M. Am. Soc. C. E., in 1936,[58] Joseph Kittredge, Jr., in 1938,[59] and Gordon R. Williams, Assoc. M. Am. Soc. C. E., and others in 1940.[60] These studies have had as their aim the determination of total evaporation from watershed areas by the method of deducting runoff from precipitation. The results of these studies, however, are generally in line with those of the authors. Of especial interest is the correlation made by Mr. Williams of mean annual water loss with mean annual temperature for twenty-eight watersheds in which mean annual precipitation is in excess of 20 in. This relation can be expressed by a straight line, although the departure of individual points from the line is greater than found by the authors for consumptive use and effective heat (see Fig. 2). By eliminating consideration of temperature during the non-growing season, the authors have evidently devised a method of correlation that adheres more closely to the temperature conditions directly related to plant activity and transpiration.

The writer believes that the authors' method will bear further study and has a field of application that will ultimately be useful in water supply studies as well as in irrigation planning.

HARRY F. BLANEY,[61] M. AM. SOC. C. E.—The treatise on consumptive use of water for irrigated agriculture is excellent, and the authors have developed a practical method of estimating evapo-transpiration based on the relation of measured consumptive use to maximum temperatures above 32° F during the growing season for average water supply and crop conditions. The effect of sunshine and heat in stimulating transpiration was studied as early as 1691, according to a review of literature by the U. S. Department of Agriculture in 1905.[62] For many years irrigation and hydraulic engineers have considered the use of temperature data in estimating consumptive use of water. However, the results usually have not been satisfactory for individual years as the annual variations in rainfall, water supply, crop distribution, and methods of irrigation were not taken into account. For an average consumptive use over a series of years the method is also subject to criticism, when projects under consideration do not have similar crop distribution or the quantities of water available for irrigation per acre are materially different. The authors have made allowance for these varying conditions, but caution should be exercised by those not so familiar with the problems involved. For example, two projects having about the same effective heat unit in day-degrees might have considerable difference in average unit consumptive use if one project had 50% alfalfa and 15% cotton and the other had 20% alfalfa and 60% cotton, since alfalfa may consume 50% more water than cotton.

[62] "A First Report on the Relations Between Climates and Crops," by Cleveland Abbe, *Weather Bureau Bulletin No. 36*, U. S. Dept. of Agriculture, 1905.

Differences in distribution of crops is illustrated by a crop survey of the districts in Pecos County, Texas, made in 1940 by the Department of Agriculture in connection with the Pecos River Joint Investigation. The distribution of the irrigated acreage in the Fort Stockton area was: Cotton, 18%; alfalfa, 58%; and other crops, 24%; whereas the distribution in the Imperial-Buena Vista area some 50 miles away was: Cotton, 53%; alfalfa, 26%; and other crops, 21%. The writer computed the consumptive use by both the integration and inflow-outflow methods for these areas, finding that the consumptive use in the Fort Stockton area was considerably more than in the Imperial-Buena Vista area, although there was very little difference in the effective heat units. The greater use in the Fort Stockton area was attributed to a larger percentage of alfalfa and a more abundant water supply.

The authors mention the inflow-outflow and integration methods used in estimating consumptive use of water in the Upper Rio Grande Basin[10] in 1936. In connection with this investigation and the Pecos River study in 1940, the writer reached the conclusion that further research into the relation of available heat to consumptive use of water must be conducted to make the effective heat method comparable in accuracy and reliability to the inflow-outflow and integration methods. Tables 10 and 11 show how closely the results of the inflow-outflow and integration methods in Mesilla Valley will check under favorable conditions. However, conditions are not always favorable for use of these methods.

Before the integration method can be successfully used it is necessary to know unit consumptive use and the areas of various classes of agricultural crops, native vegetation, bare land, and water surfaces. The reliability of the method depends primarily upon the selection of proper unit consumptive-use values.

In the consumptive-use studies conducted by the Division of Irrigation in cooperation with the National Resources Planning Board on the Pecos River in 1940, the writer developed the irrigation efficiency method of determining unit consumptive use for various agricultural crops. Briefly, the irrigation efficiency method consists of estimating evaporation and transpiration losses during the growing season and winter period based on data available as to the number of irrigations and depth of water applied, farm duty of water, and efficiency of irrigation water application for various crops and soils; and precipitation and evaporation from free water surface. Precipitation may be a large factor in winter consumptive use.

A survey of irrigation conditions was made throughout the Pecos River Basin. Water superintendents, county agricultural agents, engineers, and farmers were interviewed to ascertain the quantity of irrigation water supplied to various crops, both for the growing season and the winter period. Precipita-

TABLE 10.—CONSUMPTIVE USE OF WATER IN THE MESILLA VALLEY AREA (NEW MEXICO AND TEXAS), 1936, BASED ON INFLOW-OUTFLOW METHOD[a]

Bare land, roads, etc.	3,124	0.7	2,187
Total ($a + b + c$)	110,417	2.72	300,550

tion records were collected and estimates made of the efficiency of irrigation for various crops in the different areas. The latter data were supplemented by water-application efficiency studies made on typical farms by measuring the quantity of water applied and taking soil samples before and after irrigation to determine the proportion of soil moisture available for crop transpiration use within the root zone. All this information was used to determine the unit consumptive use of water for various crops in each area. A summary of the results is shown in Table 12.

For many years the Division of Irrigation, U. S. Department of Agriculture, has been correlating observed evaporation and evapo-transpiration data as a means of estimating consumptive use of water. The writer made some studies of this character on field crops at the Denver (Colo.) Irrigation Field Laboratory of the Division in 1919. The adaptability of the evaporation pan as an index for estimating evapo-transpiration losses from moist areas was demonstrated by studies in 1931.[63] For tules growing in a large tank within the confines of a swamp area at Victorville, Calif., the percentage of consumptive use with reference to evaporation from a near-by exposed Weather Bureau pan was 95%. Evaporation from pans was used as an index of consumptive use of water on the Rio Grande in 1936,[10] and on the Pecos River in 1940,[64] when evaporation stations were established in valleys extending several hundred miles along those rivers.

[63] "Water Losses Under National Conditions from Wet Areas in Southern California," by Harry F. Blaney, Colin A. Taylor, Harry G. Nickle, and Arthur A. Young, *Bulletin No. 44*, California Div. of Water Resources, 1933.

[64] "Consumptive Water Use and Requirements," by Harry F. Blaney, Paul A. Ewing, Karl V. Morin, and Wayne D. Criddle, Pecos River Joint Investigation (Pt. IV-B) Section 2 (mimeographed report of Division of Irrigation, SCS to National Resources Planning Board, 1941).

In the Pecos River investigation an empirical formula was developed by the writer and Karl V. Morin[65] for use in computing evaporation from a lake surface and unit consumptive use of water by vegetation having access to ground water, where temperature and humidity records are available. Both evaporation and transpiration respond freely to temperature and humidity. Records of temperature, humidity, and evaporation in New Mexico and Texas were used. The first step in the process was to introduce a factor of evaporative force which is the average temperature times the percentage of (yearly) daytime hours for each month, or other time unit considered. A chart using evaporative force as ordinates and use of water in inches as abscissas was developed, on which it was found that plotted observed evaporation pan records, reduced to lake surface by the factor 0.70, appeared thereon as a fairly straight line.

From this the following general formula was developed for estimating annual unit values of evaporation from free water surface and evapo-transpiration by native vegetation for use in the integration method:

$$E = F\,K\,(114 - H) \ldots\ldots\ldots\ldots (2)$$

in which E = annual evaporation in inches; F = average temperature multiplied by percentage of yearly daytime hours = evaporative force (varying with latitude); K = constant; and H = annual average relative humidity (a percentage).

It is desirable to modify Eq. 2 when computing consumptive use of water by vegetation by substituting U for E, as follows: The annual consumptive use, U, in inches, equals

$$U = F\,K\,(114 - H) = u_s + u_w \ldots\ldots\ldots\ldots (3)$$

in which: u_s = growing-season consumptive use; and u_w = winter consumptive use. Then

$$U = f_s\,k_s\,(114 - h_s) + f_w\,k_w\,(114 - h_w) \ldots\ldots\ldots\ldots (4)$$

in which the subscript s denotes the growing (summer) season and w the winter period. The symbol f varies with temperature and latitude whereas k will vary with type of vegetation.

The advantage of the evaporative force method over the effective heat method is that it includes the factors of humidity and latitude as well as temperature and length of growing season.

The authors state (see heading "Method of Study: Equivalent Area") that "the cropped land in most agricultural valleys amounts to 85% or more of the gross area." This may be true for some federal projects but the percentage of cropped land is probably considerably less in most agricultural valleys unless areas within the general irrigated boundaries are eliminated.

In the Upper Rio Grande Basin[10] in 1936, the proportion of cropped area to gross area was 56% in the Southwest Area, San Luis Valley; 46% in the Isleta-Belen Area; and 75% in the Mesilla Valley. The author's data (heading "Description of Areas Studied: Mesilla Valley, New Mexico-Texas" (Appendix)) show only 71% in Mesilla Valley, which is more than the average valley percentage.

---

[65] "Consumptive Water Use and Requirements," by Harry F. Blaney, Paul A. Ewing, Karl V. Morin, and Wayne D. Criddle, Pecos River Joint Investigation (Pt. IV-B) Section 2 (mimeographed report of Division of Irrigation, SCS to National Resources Planning Board, 1941), p. 104.

The Division of Irrigation has computed the annual consumptive use of water by the inflow-outflow method in Mesilla Valley for the period 1921 to 1939, inclusive, and the results check closely with the data given in Table 4, varying from 1.86 acre-ft per acre in 1921 to 3.53 in 1926, with an average of 2.78 acre-ft per acre for the 19-yr period.

Conditions are not always favorable or the expense may be too great to use some of the foregoing methods.

The authors have developed a simplified and unique method for estimating consumptive use under average conditions when a limited time is available. The paper is a valuable contribution to the literature on the subject.

J. L. BURKHOLDER,[66] M. AM. SOC. C. E.—The method originated by the authors provides for estimating the consumptive use of water in agriculture by correlating mean effective heat, and such consumptive use on extensive areas of cropped land having a range of climatic conditions. The adaptation of mean effective heat as the independent variable for estimating consumptive use is based on the fact that this variable is readily determinable for any locality and on the theory that it is the most important factor influencing the quantity of water consumed by transpiration and evaporation from cropped areas.

A number of other variables affect the consumptive use of water in agriculture. Some of the more important are: Soil types; alkali and drainage conditions; types of crops and their yields; and water application with respect to deficiency or surplus.

On irrigated areas, soil types, and alkali and drainage conditions constitute a complex network of factors that influence the consumptive use. If drainage is quite effective, the net influence of these factors is likely to result in a higher or above normal consumptive use due to increased evaporation losses from heavy and frequent irrigation. In the reverse case of tight soils and restricted drainage, the "rise of salt" will prove an effective brake to over-irrigation, which would increase evaporation losses. Thus consumptive use might be lowered.

The yield of most common crops under given soil and climatic conditions will vary directly with the quantity of water beneficially applied. For instance, sugar cane will normally increase its yield about 20% for each additional acre-foot of water so applied up to a total application of about 5 acre-ft. Heavy crop yields transpire more water; hence the consumptive use is increased.

On most irrigated projects water is provided to the farms in normal years practically on a demand basis. Only in years of deficient supply is the use curtailed by rationing. The authors have attempted to correct their data for any deficiency in water supply. However, without detailed information on the type of crops produced on the various farms, and on the quantity of water required for each crop, it would be very difficult to establish the amount of the deficiency. Also, under the authors' method of estimating consumptive use, it may be equally important to correct for excessive evaporation due to an overabundance of applied water.

---

[66] Senior Engr., International Boundary Comm., El Paso, Tex.

A consideration of the complex nature of the variables affecting the consumptive use of water in agriculture leads to the belief that the annual consumptive use for a given area may be expected to vary considerably from the mean for that area. The correlation between consumptive use and effective heat, therefore, should reflect the true value of the annual consumptive use so that the range of such use can be established.

The consumptive-use data presented in the paper include a total length of record of 42 years for nine irrigated valleys, of from 6,000 acres to 462,000 acres in area, and a total length of record of 141 years for eleven non-irrigated watersheds of from 200 acres to 5,000,000 acres in area. Of the eleven plotted points (Fig. 2) representing consumptive use on non-irrigated areas, nine fall below the line. It is thus apparent that the authors' study is based primarily on records of consumptive use on non-irrigated watersheds. Also, it is apparent that the mean consumptive use on these areas is somewhat lower than mean consumptive use on irrigated areas. This may be accounted for by the fact that crop yields are usually less on non-irrigated areas than on irrigated areas, or the lower consumptive use may be due to deficient or poorly distributed rainfall.

On the irrigated areas the length of the consumptive-use record ranges from as low as one year to as many as 13 years. For non-irrigated watersheds this record has a much narrower range of from 6 years to 14 years. By reducing the annual consumptive-use record of each area to a mean for the entire period of record, the authors seem to have given the same weight to records of one year as to records of 14 years.

The data presented for irrigated valleys do not include areas having high effective heat such as are found in the subtropical climates of southern California and southern Texas. The writer has attempted to extend the range of the authors' data by the inclusion of two such projects. This study has led to the preparation of a new chart (Fig. 4) on which consumptive-use data for the Barahona Project, Dominican Republic, and the Lower Rio Grande Valley, Texas, have been plotted, together with the data presented by the authors for individual years. It has thus been possible to define roughly the upper and lower limit of consumptive use. The writer is of the opinion that there is an additional advantage in expressing consumptive use as a zone rather than as a mean, since in investigating new projects the upper limit of consumptive use would then provide a safer basis for estimating the required maximum water supply and the capacity of canals and structures. Also, the lower limit may provide a useful gage of minimum water requirements when it becomes necessary to ration the supply.

It will be noted that line 2, Fig. 4, representing the mean of both the authors' and the writer's data, is almost identical in its relative position with line 1 based exclusively on the authors' data. However, if the position of the line representing the mean of the authors' data is fixed by the method of least squares, the authors' line is shifted to position 3.

The data for the Lower Rio Grande Valley include the consumptive use for the years 1922 to 1939, inclusive. The average cropped area for this project is 326,000 acres. Crop distributions are not known for each year, but, in

1929, 53% of the irrigated area was planted to cotton, 19% to orchards, 17% to vegetables, and 11% to grain and sorghum. The growing season includes the entire year. The valley has made rapid strides toward improvement of irrigation facilities and preparation and care of the irrigated lands in recent years, especially since 1928. In this connection it is interesting to note that consumptive use for the years 1922 to 1925, inclusive, is greater than for any of the following years.

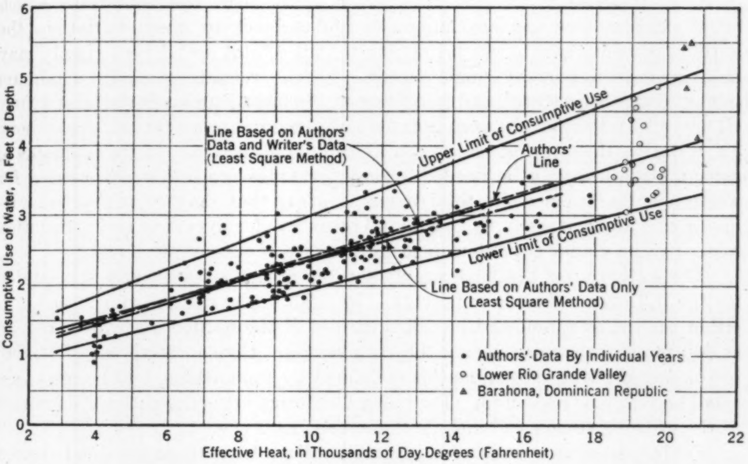

Fig. 4.—Relation of Consumptive Use to Effective Heat by Individual Years

Located on latitude 16° North, the Barahona Project is devoted exclusively to the growing of sugar cane, with the exception of a small area of pasture. Irrigation was started on this area in 1920, and the average gross cropped acreage increased from 6,332 in 1921 to 19,354 in 1924. The normal rainfall is about 12 in. and the growing season extends over the entire year. An extensive system of deep open drains was under construction during the years of record. The deltaic soils are relatively tight, and the salt content is high. These conditions forced a reduction in the quantity of water used for irrigation in 1923 and 1924.

The consumptive use for the Barahona area indicates that sugar cane uses more water than the mean requirement for similar climatic conditions as reflected by Fig. 4. The project produced an average of about 30 tons of cut cane per acre in addition to the heavy foliage that was stripped from the cane as it was harvested. It is the sole example of a single-crop area included in the study, and its inclusion results in a steepened line of mean consumptive use.

The authors have made a very able presentation of the subject, and their effort should be commended by those interested in irrigation development. Additional records of consumptive use on irrigated areas are needed to amplify and extend the study presented by them. It is hoped that this paper will stimulate engineers in charge of the many irrigation projects to undertake the required measurements and calculations in order that the range of consumptive use can be more definitely established.

Acknowledgment.—Assistance was rendered by Victor L. Streeter, Assoc. M., Am. Soc. of C. E., in preparing Fig. 4 and the data on the Barahona Project and Lower Rio Grande Valley.

S. T. HARDING,[67] M. AM. SOC. C. E.—Although the conditions which affect consumptive use are numerous and subject to much variation, the authors present records which indicate that the total useful heat supply may be the most important single factor. As the records of daily maximum temperatures are secured and published at Weather Bureau Stations in nearly all agricultural areas, the accumulated daily maximum air temperature above 32° F during the growing season can be computed for areas where estimates of consumptive use may be needed. Such estimates are frequently needed for western areas because the total irrigated areas that may be supported adequately by any water supply (where full recovery of conveyance and percolation losses can be made) are determined by the rate of consumptive use.

The authors use the heat supply for the growing season and the rainfall for the full year. This is consistent. Rainfall in the non-growing season will either appear as runoff and be taken care of in the outflow records or remain as soil moisture for use during the crop season. Consumptive use of rainfall in the non-growing season, as this is defined by the authors, will be relatively small and may be neglected. For many California areas the authors' definition of the growing season will include the entire year.

Table 1 separates results for irrigated valleys from those for non-irrigated watersheds. The latter are similar to the watersheds for which other computations of consumptive use have been published in *Water Supply Paper No. 846*.[68] The water losses (as this term is used in *Water Supply Paper No. 846*) are equivalent to the authors' definition of consumptive use, since adjustments were made for the loss from water areas. The values of the resulting mean annual water loss in *Water Supply Paper No. 846* for eighteen different parts of the drainage area of the Delaware River vary from 16.9 in. to 32.8 in. although the precipitation varied only from 92% to 110% of the mean of 44 in. These results are secured from more general records than those used by the authors and would be expected to vary more widely. The authors limited the records they used to areas which they considered to be fully supplied with moisture; the rainfall in the Delaware Basin should be sufficient to approach or exceed this standard. An application of the authors' method of comparison of effective heat and consumptive use to the results shown in *Water Supply Paper No. 846* would indicate the range of variation to be expected where only such general records are available.

The authors make a distinction between the consumptive use on agricultural and nonagricultural areas and reduce their results to the rate of consumptive use per acre of cropped area. Allowance when needed, both for areas using only rainfall and for areas of swamp or other excess rates of use, is essential if results applicable to crop areas are to be secured. The authors' procedure for such areas and the amount of the differences made for these lands are not consistent, however, with their treatment of all crops as having the same rate of consumptive use. They state that, notwithstanding the wide differences in crops in the areas used (mountain meadow hay and alpine forests to cotton and citrus fruits), the relation between consumptive use and effective heat is maintained closely. This should not be accepted too completely. The close relationship shown in Fig. 2 appears to be the result of balancing factors in the different areas rather than the uniformity of use by different crops. In several of the areas listed grain can be grown without irrigation with rainfalls less than the amount of the consumptive use shown. The differences in the moisture requirements of forage and orchard crops are also recognized in irrigation practice. The relationship shown in Fig. 2 would need to be modified when applied to local areas to allow for the types of crops to be grown.

[67] Prof., Irrig., Univ. of California, Berkeley, Calif.

[68] "Natural Water Loss in Selected Drainage Basins," by G. R. Williams and others, *Water Supply Paper No. 846*, U. S. Geological Survey, 1941.

The points plotted in Fig. 2 fall as consistently along the straight line used as can be expected in results of this type. This does not mean that this line can be extended outside of the range of these records, however. Its extension downward would indicate a consumptive use of about 1 ft in depth, per year, in an area having no effective heat. This is a probable value as yearly moisture losses on an area where the climate permits any growth of vegetation or evaporation from the soil would be expected to approach this amount. The authors' points 18 to 20 indicate that the extension of the curve upward should be on a reduced slope reaching a maximum consumptive use somewhat above 3 ft per yr.

Such a maximum consumptive use under large values for effective heat is also indicated by other records. The maximum values for effective heat in the United States are about 20,000 day-degrees F per yr. This value occurs on the lower Colorado River areas in Arizona and California. For such amounts of effective heat the extension of the line in Fig. 2 gives a consumptive use of about 4 ft per yr. This is about the average rate of delivery to the land of irrigation water plus rainfall in the Imperial Valley and exceeds the similar figure for the Yuma Project. The delivery to the land in both of these areas includes some deep percolation losses not consumed by the crops so that the actual consumptive use will be less than that indicated by Fig. 2. This does not mean that the relationship in Fig. 2, within the limits of its supporting data, is incorrect; but it indicates that, in areas of greater effective heat, consumptive use should reach a maximum at or greater than 3 ft per yr. In such areas it is not customary for land to be fully cropped for the entire year and this difference is the result of not utilizing the full available heat supply.

The authors have included rainfall in the water supply from which the consumptive use is determined. This is desirable in results that may be used in both irrigated and nonirrigated areas. In some parts of California the rainy and irrigation season are sufficiently separate that values of the consumptive use may be derived which are applicable to the irrigation supply only. This practice is useful in these areas in determining the irrigation supply that needs to be provided but such results should not be applied to areas having different amounts or distribution of rainfall without making allowances for this difference in the basis of the results. The consumptive use from irrigation separately from the rainfall has been determined for some areas served by Kings River,[69] in California, the values derived being about 1.7 ft for orchards and vines and 2.0 to 2.25 for areas mainly in alfalfa. The mean rainfall is about 0.75 ft occurring during the winter months and should be added to these figures to give results in the terms used by the authors. Effective heat is available in all months of the year and some growth occurs throughout the year. Consumptive use by the trees and vines during their dormant period is replaced by the consumptive use of volunteer or planted cover crops, which receive their moisture supply mainly from the rainfall. The total annual effective heat for Fresno, Calif., is about 16,000 day-degrees for which Fig. 2 indicates a general consumptive use of 3.4 ft. This is a larger rate of consumptive use than the local records support and agrees with the indications of the authors' points 18 to 20 that consumptive use by crops will seldom exceed 3 ft.

C. S. JARVIS,[70] M. AM. SOC. C. E.—An unusual, although apparently logical, approach to a difficult problem has been used by the authors, and they have brought forth interesting as well as concordant data concerning water use on the various projects and regions dealt with. These data agree so closely with the fragmentary information heretofore available, and supplement the previous authoritative statements so satisfactorily as to call for a continuation of the research to cover many more river systems.

The writer's recent approach to consumptive use of water within a number of river basins was incidental to tracing the variations of annual or other periodic river discharge as related to recorded precipitation. It became apparent, for example, in dealing with the upper Missouri River and the entire Platte River basins, that the yield from the headwaters and the precipitation were closely related for separate years, pairs or groups of years, such as decades, and up to the total periods of record, whereas the recorded discharges along the middle valleys showed more and more marked deficiency as the irrigated area, and the storage facilities serving such regions, became further developed. So persistently were these deficiencies displayed within the main irrigated regions that it became advisable to make an evaluation of such "increased consumptive use due to irrigation and storage projects." It thus appears that the quantities derived by the writer are not strictly comparable to those published by the authors, although there is some fairly close relationship. Any river basin in the arid region on which considerable regulation and utilization of its water resources have been achieved should show a marked reduction of outflow as a result of such development. For example, the Platte River discharging at Ashland, Nebr., can be reconciled with the summation of inflows from its four main tributaries only by allowing for some 1,600 cu ft per sec as representing consumptive use due to irrigation developments during recent years in the lower valley, as shown in Table 13.

[70] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

Similarly, the Missouri River discharge at Fort Benton, Mont., averaging 4,608 cu ft per sec for the 5-yr period from 1934 to 1938, apparently should be increased by about 1,400 cu ft per sec to account for the increased consumptive use due to irrigation in upstream areas.

Utilizing the 1930 census data on "irrigation of agricultural lands," as shown in Table 14, and calculating the consumptive use for irrigated acreage in accordance with the quantities given in Tables 1 to 6, produce the results in the final columns of Table 14, some of which are but estimates, while others are official record data. It is obvious that the most nearly complete utilization of water resources among the larger drainage basins as of 1929 was along the

Platte River, in Colorado and Nebraska, where increased consumptive use due to irrigation in the entire valley nearly equals the average outflow discharge at Ashland, within 25 miles of the Missouri River. However, if the Platte River discharge is measured near Duncan, Nebr., instead of at Ashland, the 10-yr average is 1,668 instead of 4,968 cu ft per sec, thus indicating that more nearly $\frac{4{,}780}{4{,}780 + 1{,}668} = \frac{4{,}780}{6{,}448} = 74.1\%$ of the available discharge is utilized within the region where irrigation is required, instead of approximately 50% of the total above Ashland including some areas where only supplemental if any irrigation is needed. Both the Great Basin and the Rio Grande drainage areas show utilization of water representing slightly more than 40%, computed as in the foregoing, for the year 1929, whereas the San Joaquin and Colorado River basins show 29.6% and 24.1%, respectively.

It is known that in many small drainage basins, components of the larger ones listed in Table 14, the utilization has closely approached 100% in recent years. However, where open storage over a long period is required to accomplish such development, considerable actual loss is necessarily entailed through evaporation, year after year, in addition to the inevitable deep percolation and seepage, small or otherwise in amount, which deplete the outflow without

TABLE 14.—IRRIGATED ACREAGE AND ESTIMATED CONSUMPTIVE USE OF WATER FOR IRRIGATION IN 1929

Drainage system	1930 census irrigated acreage of 1929	Estimated average consumptive use, in cu ft per sec	Record-period average discharge, in cu ft per sec [a]	Estimated utilization for irrigation; 1929 (%)

[a] Unofficial estimates or derivations are in parentheses.

adding materially to crop growth of such basins, thus reducing the net amount available for use.

Now consider the fact that the Mississippi River discharge at its mouth represents approximately 25% of the precipitation within the entire basin, with the Ohio River and smaller tributaries from the eastern portion yielding more nearly 50%, while the river systems draining the Great Plains area yield more nearly 5% to measurable channel discharge and undetermined amounts to subsurface flow. Then the high utilization percentage of the Platte River (74.1 at Duncan or 48.9 at Ashland) applied to 5% runoff yield, results in only 3.7% or 2.5% of the precipitation which the consumptive use for irrigation diversions may represent, even though it largely depletes the Platte River discharge. The consumptive use due to both natural agencies and artificial devices or practices represents more than 96% of the total rainfall, with less than half the optimum moisture requirements maintained throughout more than 90% of the drainage basin, and only about 10% of the area adequately supplied, the irrigated and high mountainous areas with plentiful moisture being of nearly equal extent, or about 5% of the basin area in each classification. Furthermore, it is evident that the limit of practicable irrigation development within the Platte River basin is within view, unless importations of additional volumes are to be accomplished.

R. W. DAVENPORT,[71] M. AM. SOC. C. E., AND GORDON R. WILLIAMS,[72] ASSOC. M. AM. SOC. C. E.—In the period from 1935 to 1939, the writers participated in studies,[73] made by the U. S. Geological Survey, which produced results that may be compared with those presented in the paper. The studies consisted of the determination of natural water loss (or consumptive use) for about 200 non-irrigated drainage areas in humid and sub-humid regions east of the Rocky Mountains. The areas studied are similar to areas 10 to 20, in Table 1.

The relation between temperature and consumptive use was determined for only twenty-eight areas and in the published report[73] mean annual temperatures were used instead of day-degrees. It was realized that day-degrees of mean daily temperature above 32° might give a better correlation than mean temperatures. In order to determine the relation between mean temperature and day-degrees above 32° for yearly periods, the records for twenty-three representative stations, totaling sixty-nine record years, were studied. The results of the study were plotted and a mean curve drawn.[74] This curve showed that, for mean annual temperatures above 48° F, the mean temperature should give as good a correlation as total day-degrees.

Beyond showing the relation between the two methods of indicating temperature no use was made of this curve but it could be used to change the mean annual temperature to equivalent total day-degrees above 32° F. This has been done for the purposes of this discussion and the results are shown in Fig. 5. The plotted points in Fig. 5 are identified by their numbers as follows:

28	Angelina River near Lufkin, Tex.

The consumptive use was originally computed in inches but has been changed to feet to be comparable with the authors' study.

The differences in procedure between the two studies are listed in Table 15. The greatest difference lies in the method of determining effective heat. If the authors' curve from Fig. 2 is drawn on Fig. 5, a close similarity is shown in the slopes and positions of the curves even though the bases for computing the total day-degrees are different. The conclusion to be drawn is that the two methods of computing effective heat have compensating influences, that they lead to similar totals in day-degrees and are perhaps equally effective methods of correlating consumptive use to climatic conditions.

There are notable differences between the irrigated valleys and non-irrigated watersheds studied, shown in respect to altitude and various climatic features. Moreover, the way in which the water supply comes to the land is different, that for the irrigated valleys coming to a greater degree in a time when the capacity for use is greater. In view of these differences the correspondence of the relation between consumptive use and effective heat for the two kinds of areas is especially interesting and suggests that here also compensating influences are in operation.

[a] "Natural Water Loss in Selected Drainage Basins," by Gordon R. Williams and others, *Water-Supply Paper No. 846*, U. S. Geological Survey, 1940.

ROBERT L. LOWRY, JR.,[75] M. AM. SOC. C. E., AND ARTHUR F. JOHNSON,[76] ASSOC. M. AM. SOC. C. E.—The constructive criticism evoked by this paper is gratifying to the writers. The paper as submitted was recognized as only a step toward the solution of the problem of using water for irrigation. It is hoped that as new studies are completed the results may be made available to the profession.

Criticism of the paper has centered largely around the following items:

(*a*) Failure to use plot and tank experimental data;
(*b*) Lack of California projects in the study; and
(*c*) Poor correlation when analyzed by statistical methods.

When reviewed carefully in relation to the purpose underlying the study, none of these criticisms afford a basis for casting doubt on the results as reported.

---

[75] Engr., National Resources Planning Board, Denver, Colo.

[76] Engr., Bureau of Reclamation, Denver, Colo.

The answers to the foregoing criticisms may be stated briefly thus:

(*a*) Field-plot experimental data are not applicable to valley consumptive use. They are undoubtedly valuable for indicating specific losses by certain crops, but their application to field conditions depends upon too many unknown factors.

(*b*) An attempt was made to find data on California areas that could be analyzed on a basis comparable to that used on material included in the study. No place was found where inflow-outflow records are adequate, and the assumptions required to fill in missing records would practically invalidate results.

(*c*) Because of the nature of the computations, the varying accuracy of the data involved, and the assumptions necessary to the study, the results do not lend themselves to strict statistical analysis, and any such treatment should be made with care. For the purpose of this study, this fact in no way affects the conclusions that have been drawn.

Many other of the criticisms have apparently been due to a lack of complete understanding of the methods used in the computations or of the method of locating the consumptive-use curve.

By reference to studies of algae in Los Angeles reservoirs, Mr. Lee criticizes the writer's statement that growing-season temperatures more nearly parallel the cycle of plant growth than does solar radiation. The life cycles of most varieties of algae are not similar to those of plants normally grown in agricultural practice. The observed increase in algae concentrations in the spring, when solar-radiation intensities are high (and incidentally, when food supplies are abundant because of the spring turnover of the water), may mean only that there are more individuals at that time rather than that each individual is making the greatest growth in its life cycle. Further, the reference loses significance when it is considered that algae do not consume water in the same sense that higher types of plants do. From a practical standpoint solar radiation cannot well be used as a measure of consumptive use because of the dearth of records. Only twenty-one stations measuring solar radiation are listed by the Weather Bureau for the United States, of which only two (Lincoln, Nebr., and Albuquerque, N. Mex.) are between the Mississippi River and the Pacific Coast.

Mr. Foster has attempted to show that there is no correlation between effective heat and consumptive use. The writers have no criticism of Mr. Foster's mathematics but point out that by confining his computations of correlation coefficients to individual areas, all but one of which are nonirrigated, and averaging the individual coefficients, he has ignored the writers' premise that over a wide range of conditions a very high correlation exists between effective heat in the growing season and consumptive use. For any one area, effective heat varies relatively little from year to year as compared with consumptive use because of the effect on the latter of variations in the accuracy of records, distribution of rainfall, changes in crops, inroads by pests, and effect of management. Over the entire range of climatic conditions the variation in effective heat, a universal factor, is large as compared with the variation caused by more or less local factors. The correlation coefficient for a series consisting of the mean values of effective heat and consumptive use for each study area was found to be 0.974 by Eq. 1 quoted by Mr. Foster. Similarly, a sample consisting of the effective heat and consumptive use values of that year which varied most from the curve of Fig. 2 from each study area gives a correlation coefficient of 0.70.

Messrs. Davenport and Williams have raised the question of correlating consumptive use with effective heat as estimated from daily temperatures. Although mean daily temperatures show an excellent correlation, maximum daily temperatures were found by the writers to show a better one, primarily, it is believed, because maximum temperatures reflect better the effect of radiant solar energy available only during daylight hours. Fig. 5, presented by Messrs. Davenport and Williams, does not give a true comparison of methods because effective heat for the study areas was computed by only one method.

In discussing the paper at the time it was presented before the Irrigation Division, Royce J. Tipton, M. Am. Soc. C. E., suggested that consumptive use be correlated with mean annual temperatures. This gives a very good correlation and offers a somewhat simpler computation than the writers' method. It is also of somewhat wider application because mean annual temperatures are frequently published for stations for which daily maximum and minimum temperatures, though available at central offices, are not published. Mean annual temperatures, however, do not reflect differences in growing-season temperatures, as was stated by Mr. Debler in comparing the Klamath Project in Oregon and California with an eastern Montana area such as the Lower Yellowstone Project. The mean annual temperatures at Tulelake, Calif., and Glendive, Mont., for the period 1933 to 1939 were 46.7° F and 45.9° F, respectively, but growing-season effective heats were 6,890 degree-days and 8,760 degree-days, respectively.

Mr. Rule criticizes the writers' method of determining effective heat, first for using a base of 32° F, and second, for the tedious work involved in computing the length of the growing season. He states that a base of 52° F would probably fit the Mesilla Valley better than 32° F. This may be true, but the same cannot be said for the cold New Fork and Michigan-Illinois areas where a base as low as 25° F would probably be better. The writers chose a base of 32° F after much study, as it appeared to give the best results over the entire range of climatic conditions represented by the study areas. Computation of the end points of the growing season is seldom tedious because these points can be picked by inspection in most cases, with recourse to the weighting process only in questionable cases.

Mr. Blaney suggests the irrigation efficiency method of determining consumptive use as an improvement over the effective heat method. As he states, that method

> "* * * consists of estimating evaporation and transpiration losses during the growing season and winter period based on data available as to the number of irrigations and depth of water applied, farm duty of water, and efficiency of irrigation water application for various crops and soils; and precipitation and evaporation from free water surface."

Such data would not be available for an undeveloped irrigation project. The purpose of the method proposed by the writers is to furnish estimates of consumptive use in areas where no past records are available. Mr. Blaney compares the method directly with the inflow-outflow and integration methods. The inflow-outflow method is basic for the determination of consumptive use under existing conditions where all factors can be measured. The integration method is one of approximation where inflow-outflow methods cannot be applied readily but where data on the relative areas in various classes of vegetation can be secured. It can be applied to a new area only if the consumptive-use requirements of the crops to be grown on the area are known. The effective heat method serves the latter purpose by referring to average requirements as indicated by effective heat. As Mr. Jarvis points out, the method also may be used in connection with estimates of runoff from precipitation, but it was not developed with this in mind. Because of errors in annual estimates of consumptive use due to local influences other than temperature, this application should be confined to averages unless more dependable methods for estimating annual runoff values are lacking.

Mr. Lee suggests that the master curve be supported by points based on eliminating non-growing-season precipitation, except as such precipitation can be stored in the soil at the beginning of the growing season, or that growing-season precipitation alone be included. In so doing, he does not distinguish between the development of the curve and its application. In developing the curve from inflow-outflow data, precipitation is a part of inflow and runoff from precipitation not consumed—a part of outflow. Therefore, precipitation must be included in the total. In application, only that part of precipitation adjudged available for plant use or soil storage for plant use is considered effective, and the remainder is discounted as runoff or deep percolation. The effectiveness of precipitation varies widely, depending upon its intensity and amount, its distribution through the year, the character of the soil, the surface slope, and the vegetative cover. Under normal conditions it is probably 75% to 100% effective during the growing season according to the writers' definition. Under conditions of low winter precipitation, characteristic of the Great Plains, rainfall may be insufficient to supply winter consumptive-use requirements, and consequently the soil dries out. Irrigation then becomes necessary in the spring, before planting. On the West Coast winter precipitation normally exceeds the winter consumptive use, and the excess over that used or stored in the soil is lost.

There is little information on which to base the monthly distribution of consumptive use for estimate purposes. The writers frequently have based estimates on the monthly determinations for the Mesilla Valley and the Boise Project, and on various tank and plot experiments. Fortunately, the soil-moisture reservoir is usually sufficient to provide for most errors of estimating the monthly distribution of water for irrigation.

Mr. Burkholder suggests that because of the greater number of years of record for the humid areas included in the writers' study it is apparent that the latter is based primarily on consumptive use by non-irrigated areas. This is not the case because, as Mr. Burkholder himself states, nine of the eleven points representing non-irrigated areas fall below the curve. The curve was based on results from irrigated areas, and the non-irrigated areas were added merely as a general check on the validity of the conclusions. Least-square methods were not used as the data represents studies of varying length and dependability. The curve was established on judgment, with the greater weight given to the records believed to be the more dependable. Fig. 6 shows the curve in relation to irrigated areas alone.

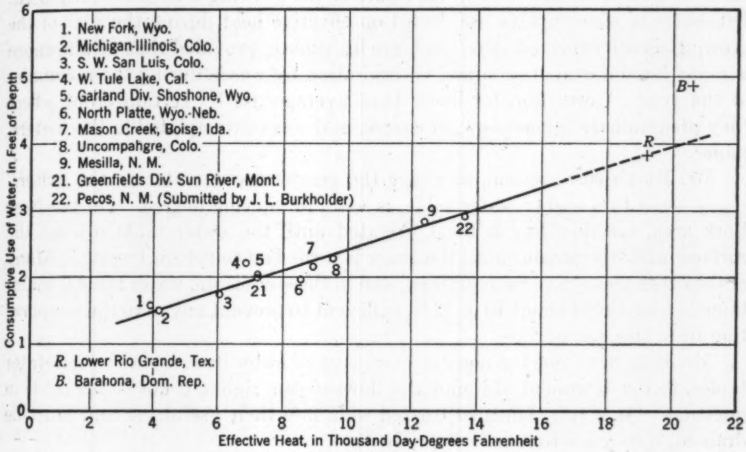

FIG. 6.—RELATION OF CONSUMPTIVE USE TO EFFECTIVE HEAT-MEANS FOR IRRIGATED AREAS

Mr. Burkholder also suggests using curves for upper and lower limits of consumptive use rather than the average value indicated by the curve presented. This suggestion appears useful for investigation studies. The upper limit could be used in determining system capacity and the lower limit as a criterion of minimum requirements in lieu of the usual allowance of a permissible shortage for the driest years.

Professor Harding and Mr. Rule criticize the writers' curve as not applicable to California and the Southwest. Mr. Rule's three suggested reasons for the apparent discrepancy, especially economic conditions and type of crops, are believed a reasonable explanation of a part of the difficulty. The writers have noted a tendency among California investigators to discount precipitation and ground-water movement toward heavily pumped areas, and a part of the difficulty may be attributed to these factors. The curve was designed to represent conditions of liberal use of water on general crops suited to the climatic conditions indicated by the growing-season temperatures and with full utilization of the growing season. Normal evaporation of moisture from precipitation, even though that precipitation is of no direct benefit to plant growth, is included as a part of consumptive use. It is well known that, through a wide range, crop production increases with an increase in water applied, but the most economical application depends upon the relative cost of the increased application to the value of the incremental gain in production. The relation varies, too, with soil fertility and character of the crop. Doubtless, because of the limited surface supplies, the high cost of pumping, and the favorable climatic conditions for growing fruits, vines, and certain row crops in addition to winter grain, which can utilize the winter precipitation with little need for irrigation, Central and Southern California consumptive uses appear low in comparison with the curve values, even when a correction is made to limit effective heat to that part of the growing season actually used. Estimates of consumptive use, based on effective heat during the part of the growing season expected to be used, are legitimate, provided that an allowance is made for soil evaporation and transpiration by weeds during the remainder of the year. Correction for lower than average use by certain crops where they predominate is necessary, of course, and was contemplated in the writers' paper.

Mr. Rule's third reason, ascribing the greater use of water on the writers' study areas to a higher water table, is valid in varying degree. On the New Fork area, meadow hay is flood irrigated until the water table reaches the surface, where it remains until the water is turned off to permit haying. Many of the other areas have been drained, and in these cases the water table is maintained at depths of about 10 or 12 ft, sufficient to prevent any material evaporation from this source.

Mr. Rule mentions the possible excess use of water by areas with high water tables, to the detriment of junior and downstream rights, if not to the lands in question. As a rule, lands so treated soon lose their usefulness and must be drained, if they are to remain in production.

By way of recapitulation, Fig. 6 is presented to show the writers' curve of consumptive use in relation to effective heat supported by data from irrigated areas only. Mean values for the Lower Rio Grande Valley and the Barahona Project, obtained from annual values given by Mr. Burkholder in Fig. 4, are shown on the graph for comparative purposes, but the writers have not had the opportunity to examine the basic data supporting them.

AN INVESTIGATION OF PLATE GIRDER WEB SPLICES

By J. M. Garrelts,[1] Assoc. M. Am. Soc. C. E., and I. E. Madsen,[2] Jun. Am. Soc. C. E.

With Discussion by Messrs. C. H. Gronquist, Charles Stratton Davis, Bruce Johnston, Francis L. Castleman, Jr., and J. M. Garrelts and I. E. Madsen.

Synopsis

In the design of plate girders several types of web splices are in current use. Probably the most common is the type with one plate on either side of the web extending the full depth between the toes of the flange angles. This splice was investigated by the writers both for the condition of uniform rivet spacing and for that of nonuniform rivet spacing. The six-plate splice, with three plates on each side of the web between the toes of the flange angles, two for moment and one for shear, was also investigated. The other type considered was that in which the web is spliced for its full depth between the toes of the flange angles for shear and strap plates over the flange angles to splice for moment. In many cases fill plates are required under the strap plates. In most cases the cost of the splice increases with the number of pieces to be handled.

Apparently the design of such splices has been based largely on assumptions which have never been checked by tests, and even the relative merit of these various designs has been unknown. This paper reports a series of tests designed to secure information concerning the behavior of plate girder web splices under load and to determine the relative values of four types of web splice design commonly used in modern practice.

Introduction

Four plate girders, each having a depth of 24¼ in. and a length of 24 ft and identical except for the types of web splices used, were subjected to test. The procedure was divided into two main parts: (1) All girders were first tested at working stresses (that is, at loads producing stresses below the elastic limit, thus

---

affording a basis for the comparison of their behavior in the elastic range); and (2) the tests of each girder were continued to failure, in order to reveal possible variations under increased loading.

In the first phase, or elastic range tests, strain rosette readings were taken along the center line of the splice and on two parallel lines, one on each side of the splice except for G_4 where two parallel lines were used on each side of the splice. The strains were measured on three intersecting gage lines at each strain rosette with tensometers using 1-in. gage lengths. Normal and shear stresses were computed for a vertical cross section through each rosette point using the measured strains. The longitudinal stresses in the flange angles and cover plates were determined from additional strain gage measurements on these elements using tensometers with 0.5-in. gage lengths. The variations in direct and shear stress intensities over the full depth cross section of each girder are given by curves drawn to represent the intensity of stress at any point. The variations along the girder of the longitudinal stresses in the toes of the vertical legs of the flange angles are also given by curves drawn to represent those stresses.

[a] See Fig. 1. [b] 1 kip = 1 "kilo-pound" = 1,000 lb. [c] Applied shear = 16 kips in each case. [d] Splice.

During the second phase, or ultimate load tests, 10-in. strain gage measurements were taken, from which the relative rotation and the relative vertical displacement at the splice were computed. The stresses at the top and bottom of the splice plates and in the adjacent toes of the flange angles were determined from 2-in. strain gage measurements.

Although the results are given in terms of stresses, these have been computed on the basis of a constant proportionality factor of stress to strain. The values given for stresses above the yield point represent strain rather than stress.

Deflections were measured by the stretched wire and scale method. A load-deflection curve for one girder is included in this report. The curves for the other girders were similar.

The total measured moment and shear on a cross section were computed by a process of summation, using the stress curves drawn to represent the measured values. The results for these values are given in Table 1 for the gage lines shown in Fig. 1.

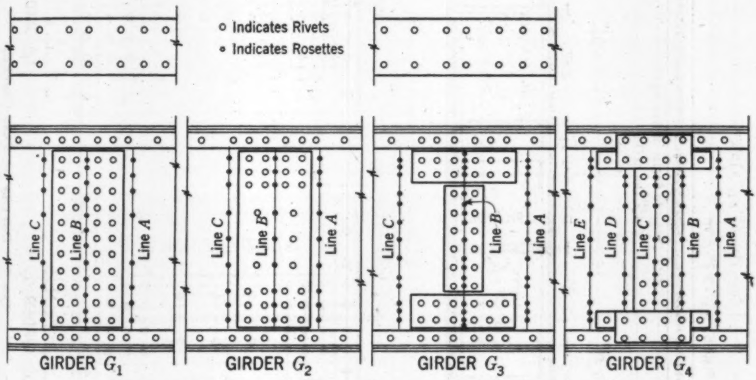

FIG. 1.—GAGE LINES FOR LOCATION OF STRAIN ROSETTES

DESCRIPTION OF TEST SPECIMENS

The dimensions of the test girders were selected by making them proportional to those of girders used in practice and as large as could be handled in the laboratory.

The four test girders were alike, except for the material and arrangement at the splices. A typical test girder, with the splices omitted, is shown in Figs. 2(*a*) and 2(*b*). The main material consisted of the 24-in. by $\frac{3}{16}$-in. web plate, four angles 3 in. by 2 in. by $\frac{3}{16}$ in., two cover plates $6\frac{1}{4}$ in. by $\frac{3}{16}$ in., and two cover plates at $6\frac{1}{4}$ in. by $\frac{1}{8}$ in. Rivets 0.5 in. in diameter were used. The girders were fabricated with a depth of $24\frac{1}{4}$ in. back to back of flange angles and a span of 24 ft center to center of bearings. The relative position of each of the splices in a girder is specified by referring to them as 1, 2, or 3 as shown in Fig. 2(*b*).

FIG. 2.—DETAILS OF TEST GIRDERS

The splice materials and the rivet arrangement for each type of splice are shown in Figs. 2(*c*), 2(*d*), 2(*e*), and 2(*f*). Each of the four different types of splice arrangement is identified by the same notation as that which is used to designate the girders; that is, G_1, G_2, G_3, and G_4.

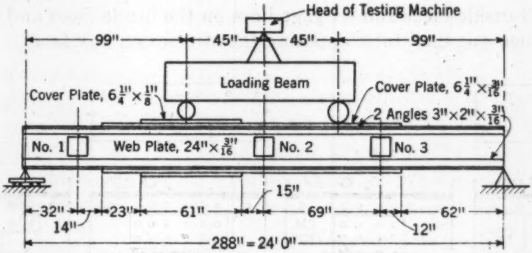

FIG. 3.—LOADING ARRANGEMENT

The preliminary test program at the time the girders were fabricated called for the application of a single concentrated load at a third point of each girder. The cover plates were designed to suit this loading condition, although the method of loading the girders was later changed to a symmetrical arrangement.

TABLE 2.—PHYSICAL TESTS ON STEEL IN GIRDER

Description	Flange angles	Web plates	3/16-in. cover plates	1/8-in. cover plates
Yield point (lb per sq in.)	43,225	32,950	31,300	33,825
Ultimate strength (lb per sq in.)	61,300	46,300	44,575	48,700
Modulus of elasticity (kips per sq in.)	29,400	29,100	29,300	29,700
Percentage elongation in two inches	46	51	55	49
Percentage reduction of area	69	71	71	69

Tensile flats were made of coupons taken from the angles, cover plates, and web plates of each of the test girders. These specimens were tested in tension to determine the yield point, ultimate strength, ductility and modulus of elasticity. The yield point stress was determined by the "drop of the beam" method. The results of the tests are summarized in Table 2.

DESCRIPTION OF TESTS

The loading arrangement used for each girder is shown in Fig. 3. The loads were applied to the girders by a 600-kip, hydraulically-operated, universal testing machine, through rollers located near the third points (1 kip = 1 "kilo-pound" = 1,000 lb). End reactions were provided by a knife-edge support at one end of the girder and a roller nest at the other end.

In the first phase of the program, strain readings were taken at 1-kip and 33-kip loads. The difference between these strain readings corresponds to a load of 32 kips which is necessary to produce a theoretical maximum extreme fiber stress of 17.6 kips per sq in. In this elastic range, a line of strain rosettes was used along the center line of splice 3, and in addition parallel lines of rosettes were taken on the web plate adjacent to the splice plates (see Fig. 1).

Longitudinal strains were measured on vertical legs of the flange angles and on both the inside and outside faces of horizontal elements of the flanges. The strains on the horizontal parts of the flanges were taken along seven gage lines on the outside faces and six gage lines on the inside faces and the average of these values was used for computing the stresses on any face.

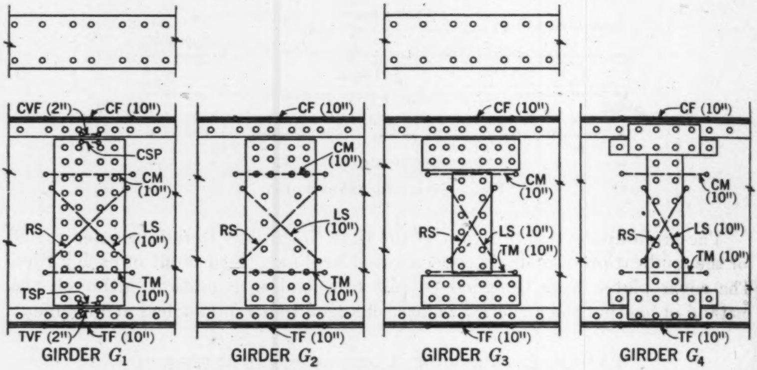

FIG. 4.—GAGE STATIONS FOR STRAIN READINGS

In the second phase or ultimate-load tests, strain-gage readings were taken at the following loads:

Girder	Initial test loads (kips)	Final increments of increase to failure (kips)
G_4	0, 1, 33, 36, 39, etc.	3
G_3	0, 11, 22, 33, 37, 41, 45, etc.	4
G_1 and G_2	0, 33, 37, 41, 45, etc.	4

Strain readings were taken at the stations shown in Fig. 4, in which:

CF = Compression flange—outstanding leg............10-in. gage length
CVF = Compression flange—vertical leg................ 2-in. gage length
CSP = Compression edge—splice plate................ 2-in. gage length
CM = Compression rotation..........................10-in. gage length
RS = Right shear strain............................10-in. gage length
TSP = Tension edge—splice plate.................... 2-in. gage length
LS = Left shear strain.............................10-in. gage length
TM = Tension rotation..............................10-in. gage length
TVF = Tension flange—vertical leg.................. 2-in. gage length
TF = Tension flange—outstanding leg................10-in. gage length

RESULTS OF TESTS

First Phase (Elastic Range Tests).—Normal and shear stresses along lines *A*, *B*, and *C* for splice 3 of girder G_1, computed from strain rosette readings, are shown in Fig. 5. Longitudinal stresses for the toes of the vertical legs of the flange angles are also shown. The curves for both measured and theoretical stresses represent the values for a 32-kip load on the girder. The gross moment of inertia of the girder section was used for calculating theoretical stresses.

Curves representing the stresses for girder G_2 are shown in Fig. 6. Stresses for girder G_3 are shown by the curves of Fig. 7. The strain readings for the flange-stress curves were taken at cross sections through the rivets and at cross sections half-way between the rivets. Although these stresses are computed from average strains they show a definite zigzag effect due to the rivets.

The stresses for girder G_4 are shown by the curves of Fig. 8 for five cross sections *A*, *B*, *C*, *D*, and *E*. Longitudinal stresses in the toes of the flange angles, where exposed, and along a corresponding line in the plates covering the angles, are also shown.

TABLE 3.—RESULTS OF BREAKING TESTS (MAXIMUM LOADS AND MOMENTS)

GIRDER G_1			GIRDER G_2			GIRDER G_3			GIRDER G_4		
Forces, in Kips		Moment (kip-in.)	Forces, in Kips		Moment (kip-in.)	Forces, in Kips		Moment (kip-in.)	Forces, in Kips		Moment (kip-in.)
Load	Shear		Load	Shear		Load	Shear		Load	Shear	
63.5	31.75	3,140	63.5	31.75	3,140	65.3	32.65	3,230	63.0	31.5	3,120

The values of the applied moments and shears, and the measured moments and shears for each of the lines of rosettes at and near splice 3, are given in Table 1. The values of the measured moments and shears were computed by numerical summation using the stresses determined from the strain readings.

Second Phase (*Ultimate Load Tests*).—From strain readings on gage lines RS and LS, splice 1 (Fig. 4), the relative vertical or shear displacements were computed and the values are given for all four girders by the curves of Fig. 9.

The relative angular displacements at splice 2, for the four girders, are given by the curves of Fig. 10. This displacement is obtained by dividing the sum of the strains on gage lines TM and CM by the 12-in. distance between these lines.

TABLE 4.—SUMMARY OF DESIGN COMPUTATIONS

Description	Web plate	G_1	G_2	G_3	G_4
For rivet group Σd^2 (in.^{2})................	....	727	719	895	960

included. The curves of load versus maximum deflection in Fig. 13 show a similar behavior for all four girders.

Stresses in the top and bottom edges of the splice plates of girder G_1 and in the edges of the adjacent flange angles are shown, for splice 2, in Fig. 14.

The ultimate loads for the girders are given in Table 3. In each case, failure was by buckling in the top flange, at splice 2 (see Fig. 15).

Discussion of Results

A summary of the design values for the four types of splices tested is given in Table 4. The design stresses and loads are as follows:

Unit stress	Kips per square inch
Bending in extreme fiber	18
Shear on gross section	13
Allowable stresses for rivets—	
Shear	15
Bearing (double shear rivets)	40
Maximum stress in plates at a distance d from the neutral axis	$18 \times \frac{d}{12.3}$
Working load, P, to produce a maximum extreme fiber stress of 18 kips per sq in	32.8
Maximum moment at working load in kip-in	(1,620)

The maximum stress in the rivet of any group due to bending is taken at the maximum bearing value. The theoretical moments and shears in the 20-in. depth of the web plates between the flange angles and the values computed from the measured strains are also included in Table 1.

An examination of the curves for direct stress reveals that at the center line of splice the stress is not directly proportional to the distance from the neutral axis. This variation is partly dependent on the relative thicknesses of the web plate and splice plates, on the length of splice plates parallel to the center line of girders and on the number of rivets in the splice plates.

Computations show that the moments carried by the splice plates on girders G_1, G_2, and G_3 are equal to the moments in the 20-in. depth of the web plate between the flange angles (Table 1). The stress due to moment in the web plate under the flange angles is taken by the flanges at the cut section. This increase in the flange stress is effective over a short length and is greater in the vertical legs of the flange angles than in the horizontal parts of the flanges.

The direct stresses along lines A and C adjacent to the spliced section of girder G_1 are essentially in agreement with the theoretical values. The curves representing the direct stresses on lines A and C for girders G_2 and G_3 and lines A and E for girder G_4 show some variation from the theoretical values. The lines representing the theoretical stresses are assumed to be unaffected by the adjacent splice.

From the data of Table 1, it is seen that the measured shear in the splice plates along the center line of splice is less than the total shear on the section. This suggests that the flange angles carry a greater part of the shear than is

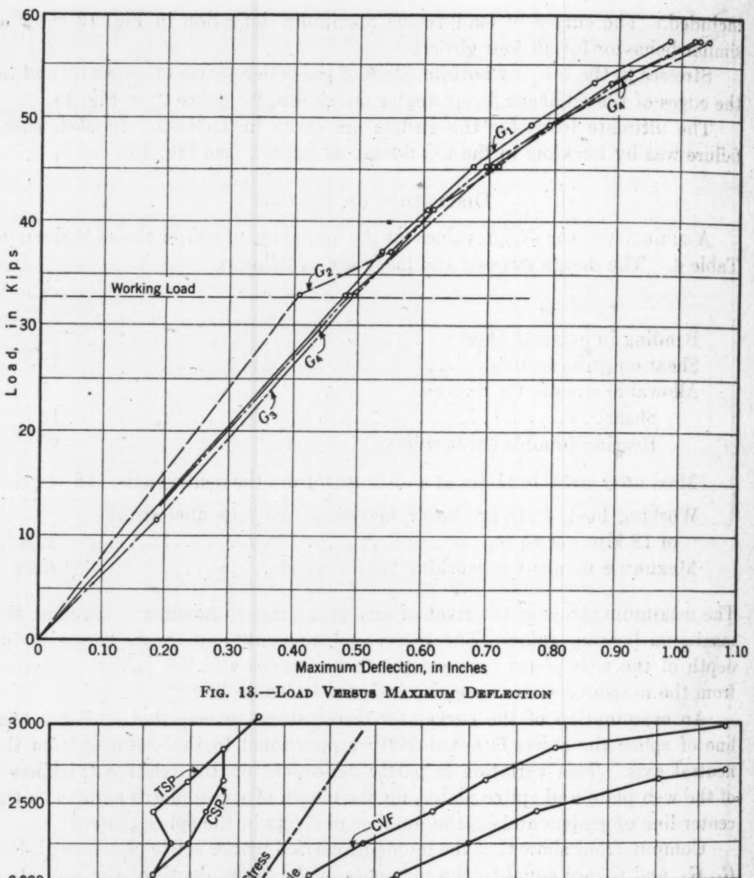

FIG. 13.—LOAD VERSUS MAXIMUM DEFLECTION

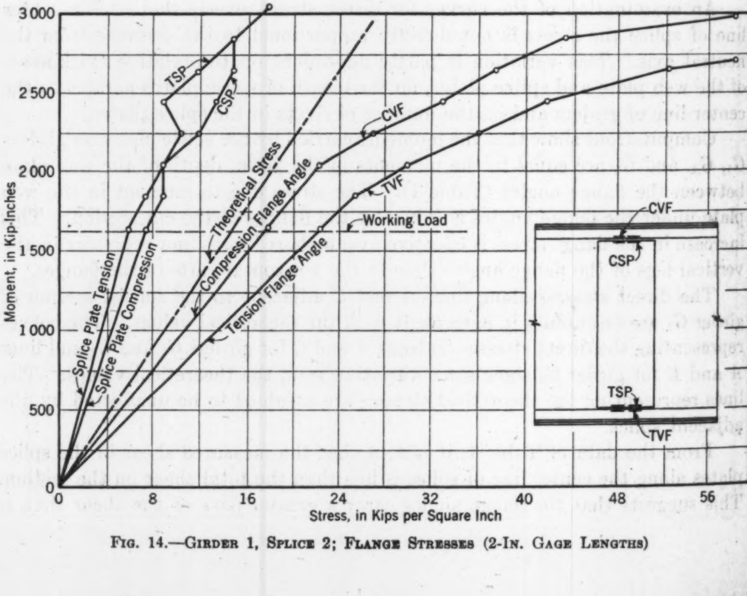

FIG. 14.—GIRDER 1, SPLICE 2; FLANGE STRESSES (2-IN. GAGE LENGTHS)

usually assigned to them. The stress curves for the toes of the flange angles show that the angles are subjected to a secondary bending stress at the cut section due to this shear. The well-known parabolic curve of shear distribution results when the loads producing the shear are farther apart than the depth of the beam. Since the loads taken by the splice plates are applied through the rivets, the shear distribution in the splice plates is affected by this method of loading the plates. There is also some disturbance in the shear curves for the lines outside the splice plates due to the adjacent splices.

The relative shear-displacement curves of Fig. 9 show a slightly different behavior for the girders. The curve for G_1 is essentially a straight line. The girders had all been subjected to the working load several times so that only the part of the curves above that load represents the action under the first application of load. The displacement at the splice on girder G_2 is about 80% greater than that of G_4 at the working load and that of G_1 is about 50% greater at that load.

The relative rotation curves of Fig. 10 show that the four splices act in a similar manner in the region of pure moment. At the working load the variation between the degree of rotation for G_3 which was minimum and G_2, the maximum, was about 25%.

The flange-stress curves of Fig. 11 show a similar behavior for the flanges of all girders. At the working load and above, the flange stresses are higher than the theoretical value based on the gross section.

The deflection curves of Fig. 12 do not indicate a noticeable weakness in any of the splices. The curves of Fig. 13 break away from the straight line at a load of about 40 kips, which is consistent with the action shown by the curves of Figs. 10 and 11.

The curves of Fig. 14 show that the stresses developed at the inside edges of the flange angles are larger than the theoretical, and the stresses in the adjacent splice plates are less than the theoretical, although both elements are essentially the same distance from the neutral axis. The curves indicate that there is a difference in these stresses for all loads and that the angles and the splice plates are acting independently. This difference is affected by the local bending in the angles and by the stress transfer through the rivets.

Behavior of the different splices was similar in character but different in degree. The action of splice G_4 was somewhat involved, but the values obtained indicate that the flange splice plates did not have enough rivets to develop the full action of the plates.

Distribution of stresses recorded during the breaking tests is consistent with that obtained for the elastic range. The buckling of the compression flanges occurred near the splice and in the region carrying an overstress due to the splicing action of the flange. Although failure did not occur in the splices, the relative actions of the four types of splices can be observed. For a girder of the type tested, there can be no failure of the splice due to moment until after one of the flanges has yielded.

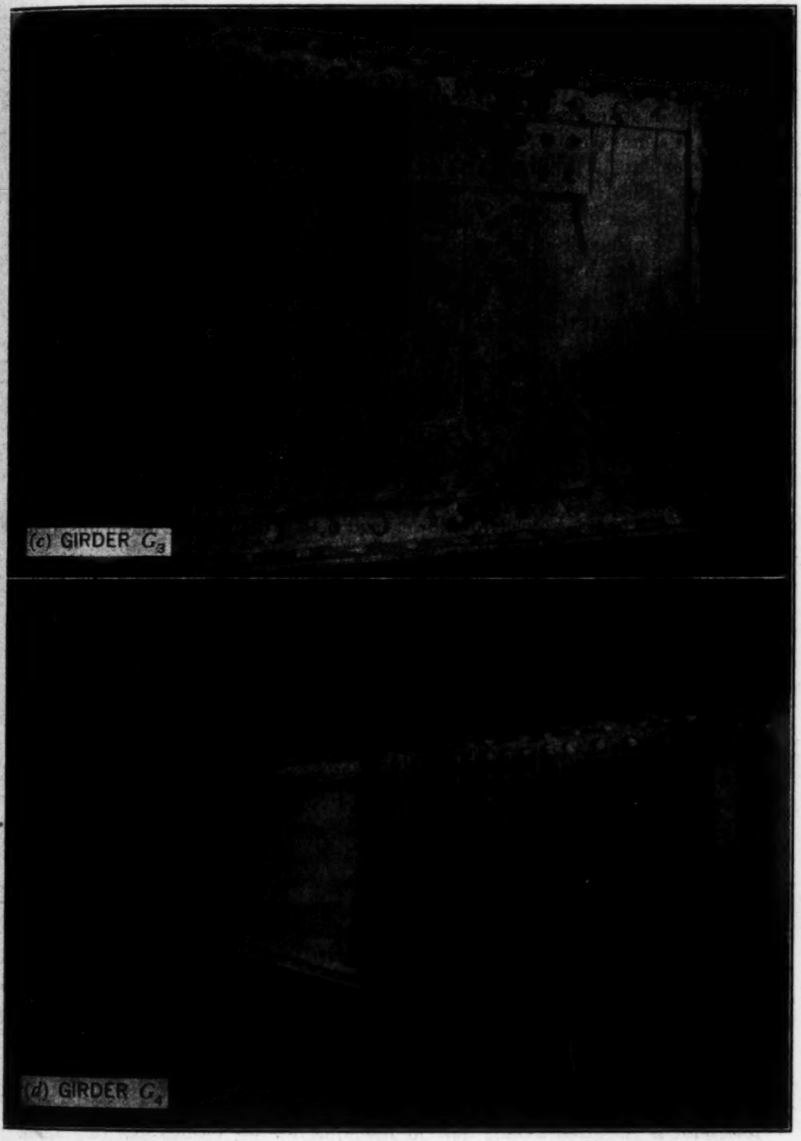
The load tests on the girders indicate the following conclusions:

(1) For all of the splices tested, each component part of any splice carried only the stress in that part of the web plate beneath that element of the splice.

(*a*) GIRDER G_1

(*b*) GIRDER G_2

FIG. 15.—VIEWS OF TEST



(c) GIRDER G_3
(d) GIRDER G_4

SPECIMENS AT FAILURE

(2) That part of the web-plate stress, not carried by the splice plates, produces an increased stress in the flanges.

(3) The splices on girders G_1, G_2, and G_3 carried only the moment in the 20-in. depth of web plate between the flange angles.

(4) At a spliced section, the component parts of the splice do not act together as a unit with the girder unless the splice is designed so that the strains in the elements of the splice are consistent with those of the girder.

(5) A splice that is weak in shear-carrying capacity will cause secondary bending stresses in the flange angles due to the shear carried by the angles.

(6) The behavior of all splices within the working load was satisfactory.

(7) The length of splice material along the girder apparently affected the action of the splices. The longer splice material of girder G_3 restrained the angular rotation at the splice. It is believed that splices of G_1 or G_2 type would have been at least as effective as G_3 in this respect if they had been extended one line of rivets on either side.

(8) A variation in the type of web splice used, between those tested, does not appreciably affect the ultimate strength of the girder if failure does not occur in the elements of the splice itself.

(9) Excess stress in the flanges, produced by the splicing action of the flanges, probably influenced the buckling of the compression flange and caused that flange to buckle at a slightly lower load than it would have for an unspliced girder.

(10) The lack of shear resistance at horizontal planes where the splice plates were discontinuous did not measurably affect the behavior of the splice.

ACKNOWLEDGMENT

The tests reported herein were planned by the American Institute of Steel Construction in cooperation with the Research Laboratories of the Department of Civil Engineering, Columbia University, New York, N. Y. Preliminary studies were made by Bruce Johnston, Assoc. M. Am. Soc. C. E., in 1938 while he was at Columbia University. The girders were designed and fabricated by the Bethlehem Steel Company.

F. H. Frankland, M. Am. Soc. C. E., and other members of the Committee on Technical Research of the Institute cooperated in the development of the program and offered valuable suggestions and criticisms as the work progressed.

The conduct of the tests was under the supervision of Prof. W. J. Krefeld, M. Am. Soc. C. E., director of the Engineering Materials' Laboratories, Columbia University, who also gave freely of his time and advice in the analysis and interpretation of results.

The authors also desire to express their appreciation for the encouragement and cooperation of J. K. Finch, M. Am. Soc. C. E., head of the Civil Engineering Department.

DISCUSSION'

C. H. GRONQUIST,[3] ASSOC. M. AM. SOC. C. E.—The investigation of stresses in plate girder web splices reported in this paper is most timely and valuable. With the increasing use of plate girders for bridges of comparatively long spans ranging up to 300 ft in length, it is proper that the theoretical bases for the design of these girders should be reviewed and checked by experimental investigation.

A type of plate girder web splice that is very frequently used was not included in this investigation. It is similar to the splices of girders G_1 and G_2, with the exception that the web splice plates are supplemented by vertical flange plates which are placed only over the vertical legs of the flange angles, and are not extended to take a row of rivets in the web splice plates as in the splice of girder G_4. This splice has the merit of providing for the cross-sectional area of the part of the web plate under the flange angles, although it does not provide shear resistance at the horizontal plane at the toe of the flange angles. According to conclusion (10) of the paper, this lack of horizontal shear resistance should not be objectionable, but it would be helpful to have the opinion of the authors in regard to this type of splice.

The flange plates, since they splice indirectly, should be extended, at least on the low-moment side of the splice, a sufficient distance to provide rivets for the transfer of the flange-stress increment in addition to those required for the splice of the web under the flange angles. This was revealed in the authors' original notes and reports, although it does not seem to have been emphasized in the paper.

CHARLES STRATTON DAVIS,[4] M. AM. SOC. C. E.—The experiments conducted by the authors to secure information concerning the behavior of plate girder web splices under load and to determine the relative values of four types of web-splice design commonly used in modern practice are most interesting and instructive.

The experiments were conducted on girders proportional to those used in practice; it might be desirable also to have some tests made on girders with excess flange strength in order to cause failure in the splices. It appears from Fig. 15 that ultimate failure occurred in the outstanding legs of the flange angles and the cover plates of the compression flanges of all girders tested. Fig. 15 further indicates that the rivet pitch in the flange plates might have been too great in proportion to the thickness of the flange angles and plates. The use of thicker material in the flanges, creating excess flange strength, might demonstrate additional information in regard to the various types of splices.

The desire to secure economical construction is an incentive that has led designers to try to splice webs of plate girders, fully, for both shear and moment and has caused the development of web splices requiring a relatively large amount of material and extra labor. Greater economy may be obtained through the use of simple splices placed at favorable locations. Flange plates are stressed to their full value only at or near their centers. They have excess flange value near their ends. It would therefore be wise to take advantage of this excess flange strength when designing web splices and place splices near the ends of flange plates. In case it should become necessary to splice the web at the center of a girder, short flange plates should be added to equal the value of the web plate in bending. It is believed that the advantages gained in simplicity of construction and resultant saving labor will more than offset all extra flange material required.

[4] Cons. Engr., Pittsburgh, Pa. (Mr. Davis died on January 2, 1942.)

Bruce Johnston,[5] **Assoc. M. Am. Soc. C. E.**—Ever since the need for these tests was first suggested in 1936 by engineers of the Bethelehem Steel Company, the writer has followed the progress of this program with interest. The authors have made a concise and able presentation of their results, and deserve much credit for their perseverance and patience in making the many strain measurements and rosette calculations.

The fact that all four splices showed nearly the same behavior constitutes an important finding applying to design economy. Splice G_1 or G_2 would obviously be the most economical, and it is interesting to tabulate the following data pertaining to the relative economy of all four splices.

Splice	No. of rivets	No. of plates
G_1	44	2
G_2	30	2
G_3	36	6
G_4	26	14

(The 26 rivets in splice G_4 do not include eight rivets in the flange angle.)

A number of years ago the writer was prejudiced against splices of the G_3 type by statements in textbooks, as well as by engineers, to the effect that this type of splice is poor design. One argument states that the splice has "four planes of shear weakness." It is interesting to have these prejudices dispelled by the fact that splice G_3 is slightly superior to the other splices on the following evidence taken from the authors' report:

(1) According to Table 1, splice G_3 carried in the working range a greater proportion of both bending moment and shear than any of the other splices;
(2) Table 3 shows that the girder with splice G_3 carried a greater maximum load than any other girder; and
(3) Fig. 10 shows that web-plate rotation at working load across the spliced part was about 14% less for splice G_3 than for any other splice.

On other counts the difference in splice behavior is extremely small, and the very slight superiority of splice G_3 is more than offset by the greater economy of splice G_1 or G_2. It is nevertheless an important fact that splice G_3 is proved to be not as bad as sometimes imagined.

---

[5] Engr., Bureau of Yards and Docks, U. S. Navy, Washington, D. C.

On the basis of Table 2 the writer has calculated the approximate weighted yield-point stress of the flange section, assuming one sixth of the area of the web to be acting therein. Assuming a linear stress-strain relationship, and using the gross moment of inertia, the maximum calculated stress at failure is only about 80% of the weighted yield-point average. The calculated stress at maximum load is very close to the weighted yield-point average if the net moment of inertia is used. It does not necessarily follow that the net moment of inertia should govern the design because there are several non-separable variables involved—for example, local bending in the flange angles at the splice, the lower-than-average yield point of the cover plates which apparently buckled first, and the unsupported length of the compression flange. However, it is true, apparently, that in the case of spliced girders of the type tested, the use of the net moment of inertia as a design basis would not appear to be overconservative. In the light of current design practice, this is a subject that warrants further study and test.

Reserve strengths more than that calculated by substituting the yield point in a maximum-stress formula are sometimes present in compact steel members, according to the principles of "limit design." Such reserve strength is conspicuously "more than absent" in the case of the spliced plate girders tested by the authors.

In their discussion of results, the authors present design data that are evidently based on the use of net moment of inertia and a maximum fiber stress of 18 kips per sq in. On such a basis the load-factor ratio, or real factor of safety for girders G_1 and G_2, adjusted from a weighted average flange yield point of 36.7 kips per sq in. to the 33 kips per sq in. minimum specified for structural steel, is calculated by the writer to be 1.73. This factor of safety is fairly well in line with the ratio of tensile yield point to working stress—that is, $\frac{33}{18} = 1.83$. If the design had been based on gross moment of inertia and a maximum allowable stress of 20 kips per sq in., the adjusted load factor of safety would be 1.32, which provides a margin of safety (between 1.0 and the tensile stress ratio of $\frac{33}{20} = 1.65$) of only 50%.

In the foregoing calculations the writer used 90% of the reported girder strength to correct the weighted average of the material yield strength of 36.7 kips per sq in. down to the specified minimum of 33.0 kips per sq in. for structural steel. Tests[6] made in 1941 on a number of different representative heats of structural steel, from different manufacturing plants, indicate that structural steel frequently has a yield point very near or even below the specification minimum of 33 kips per sq in. Such steels may show satisfactory yield points when tested at standard test speeds allowed by the American Society for Testing Materials (A.S.T.M.). Such tests are "material control" or "acceptance" tests and do not represent the minimum behavior to be expected at the slow speed of the test. The standard speed of test affects the reported yield point in the laboratory test and has little relation to the speed of loading a structure. The writer raises these questions because they are of considerable importance if the excellent service record made by plate girders in the past is to be maintained. Data available in the authors' tests have a direct relation to these questions. The subject is one that deserves more attention than has been given to it by the authors.

---

[6] "Compression and Tension Tests of Structural Alloys," by Bruce Johnston and Francis A. Opila, 1941 Meeting, A. S. T. M.

As indicated in conclusion (9), it is possible that the lower-than-yield-point buckling stresses in the flange angles may have been caused partly by local bending stresses in the flange at the spliced section. The writer suggests that the only way to make a spliced girder equally as effective as an unspliced girder may be by butt-welding the web plates before riveting the flange angles, thus eliminating riveted web-splice plates altogether.

It is obviously impossible on the basis of these tests for the authors to answer all of the questions that could be raised regarding plate girder splices. They have thrown new light on a subject that has been largely a field of speculation heretofore. Tests of this type are shown to have practical value for the engineering profession, and the authors deserve much credit for doing a difficult job in such a satisfactory manner.

FRANCIS L. CASTLEMAN, JR.,[7] ASSOC. M. AM. SOC. C. E.—The designing engineer will benefit greatly from this series of investigations. As stated in the "Synopsis," the theory of the design of plate girder web splices has been based largely on assumptions that have never been checked experimentally.

Considered broadly, these investigations give confidence in the four types of splices investigated, and designers need feel no hesitation in using any one of them. A theory does not necessarily have to be correct; all it has to do is "work"! Even casual inspection of the results of these tests shows great departure from theory, but such results that the conventional methods are quite safe and will suffice until better and more rational ones are established and accepted. Certain conclusions can be drawn from these investigations that possibly can be interpreted as suggesting minor modifications in the present theory as used.

It is difficult to choose the optimum of the four splices tested, taking into account both theoretical and practical considerations. From the latter standpoint splices G_1 and G_2 are undoubtedly the best, having fewer pieces and being more simply fabricated. Their variation in strength from the other types is negligible when considered from a practical viewpoint. They also possess a certain theoretical merit in that on lines *A* and *C*, Figs. 5 and 6, a nearer approach to straight-line theory is shown.

From theoretical considerations alone, splice G_4 probably would be preferred by most designers. However, Table 3 shows this to be located on a girder that failed under the smallest loading. In other words, assuming that the splices influenced the failure of the compression flanges, this type of splice appears to have exerted the greatest damaging influence. To the writer this is one of the most interesting features of this series of investigations. It is true that certain modifications could perhaps be made in this splice that would alter these results, but these modifications are by no means apparent upon starting the initial design. The designer has little time to ponder over such modifications even if they were finally forthcoming.

---

[7] Prof. and Head, Dept. of Civ. Eng., Univ. of Connecticut, Storrs, Conn.

Splice G_3, which is the least rational of the four types considered, shows the greatest breaking strength. This is interesting, particularly to the writer, in that he has seen this type frequently criticized (as well as most other types) as lacking certain theoretical qualifications. It would appear that the ordinary methods used in calculating the strength of such a splice are of such a fortuitous nature that they inadvertently lead to great strength.

In designs of type G_1 and G_2 it is often common to reduce the working value of the extreme rivet in the splice plate by the ratio of its distance from the neutral axis to the distance of the extreme rivet in the web (through the flange angle) from the neutral axis. Since the tests under consideration show that each component part of such a splice carries only the stress in that part of the web plate beneath it, this would seem unnecessary. Whether desirable or not, the flange acts as a separate unit in splicing the cut web at the top and bottom, and its action is entirely independent of the splice plates on the web. It is interesting to observe here that in addition to the increase in flange stress set up by the splicing action this increase also throws an extra increment on the flange rivets in the vicinity of the splice.

From a standpoint of stiffness, which is often an important consideration, most splices are usually too short. Splices of the type of G_3 will overcome this as the tests show, but the same results can be obtained by increasing the length of splices of the type G_1 or G_2. In most cases this would mean extra material, and rivets would have to be added in the interest of increased stiffness. There is no valid objection to this, if it is desirable, as the same problem frequently arises in the design of main members.

In addition to the action of the splices these investigations give a very good picture of the buckling action of the compression flanges of the girders. Using G_3 as a basis, its theoretical modulus of rupture, by proportion, would be $\frac{17.6}{32} \times 65.3 = 36$ kips per sq in. This, in itself, is not sufficient to cause failure of the compression flange, but, when the increase in stress due to sidewise buckling, plus a small allowance produced by the splicing action, is added, it is easy to understand how failure occurred. It should be noted that the yield point of the flange angles is approximately 43 kips per sq in. and that of the $\frac{3}{16}$-in. cover 31 kips per sq in. Both of these values would have to be considered, as well as the restraining influence of the web, in determining the elastic instability of the flange.

It should be borne in mind that the four girders tested to failure had top flanges that were not supported laterally, or, if so, only that small amount furnished by the loading apparatus. Furthermore, the top ends were not restrained against sidewise rotation. Such an arrangement would scarcely be met in problems of a practical nature and therefore the results can be looked upon as extreme.

With regard to shear it is unfortunate that other loading arrangements were not investigated in addition to the symmetrical arrangement used. In the elastic range considered, shearing values obtained were so small that it is questionable whether a conclusive statement could be made safely concerning the lack of shear resistance at the horizontal planes where the splice plates were discontinuous. It is often necessary to locate a splice at a point of relatively high shear, and it is in such cases that these points of discontinuity become critical. In the cases under consideration, taking G_3 as a basis and using the breaking load, the theoretical horizontal shear at the vertical toe of the flange angle in the web, using the well-known relation $\frac{V\,Q}{I\,t}$, would be 6.4 kips per sq in. at splice 3. It is also interesting to observe that, at this same point and for the same load, the theoretical stresses on a cross section due to moment fall within the elastic range (but, of course, greater than the allowable).

It would have been instructive if at least one of the girders could have been loaded in such a manner that splice 2 would have been subjected to a high shear as well as moment. As given, no shear occurs at this splice, and the loading producing such a condition is generally only of academic interest, rarely, if ever, occurring in practice. In fact, the authors state under "Discussion of Results": "* * * there can be no failure of the splice due to moment until after one of the flanges has yielded." Of course, when this has happened the girder has failed structurally.

The ideal web splice would be welded, without the use of side plates, and with the webs butted together for a V-weld or a modification of it. With such an arrangement, and using coated electrodes, stress conditions would be practically the same as in the adjacent unspliced parts of the web. As yet there is no ideal riveted splice in the sense that a stress condition is set up similar to that in the unspliced web. The writer questions seriously if such a riveted splice, or a rational solution for it, can be devised. The rivets create so many individual load points that the consequent complicating ramifications become enormous and defy rigid theoretical analysis. However, experience, and the investigations under discussion, have shown ably that the present methods are adequate, even if they are not based on entirely sound theory.

J. M. GARRELTS,[8] ASSOC. M. AM. SOC. C. E., AND I. E. MADSEN,[9] JUN. AM. SOC. C. E.—The criticisms and suggestions offered by discussers have added to the value of the paper as a record of tests made to increase the present knowledge of the behavior of plate girder splices.

The writers are of the opinion that a splice like either G_1 or G_2, with the addition of vertical flange plates as suggested by Mr. Gronquist, would provide ample splicing action for the cut web, but the distribution of stresses in the splice material will be somewhat complicated, as for example, in splices G_3 and G_4.

Mr. Davis has suggested that it might be desirable to have some tests made on girders with excess flange strength in order to cause failure in the splices, but the writers believe that the flanges in a plate girder will fail, at least as soon as the web splice. In other words, before the splice can yield in shear or bending, the flange must also yield. The location of a web splice near the end of a flange plate would provide reinforcement for the direct stress in the flange and, of course, would be preferable to splicing at a point where the flange stresses are high, unless the flange is reinforced.

[9] Capt., U. S. Army; Medford, Mass.

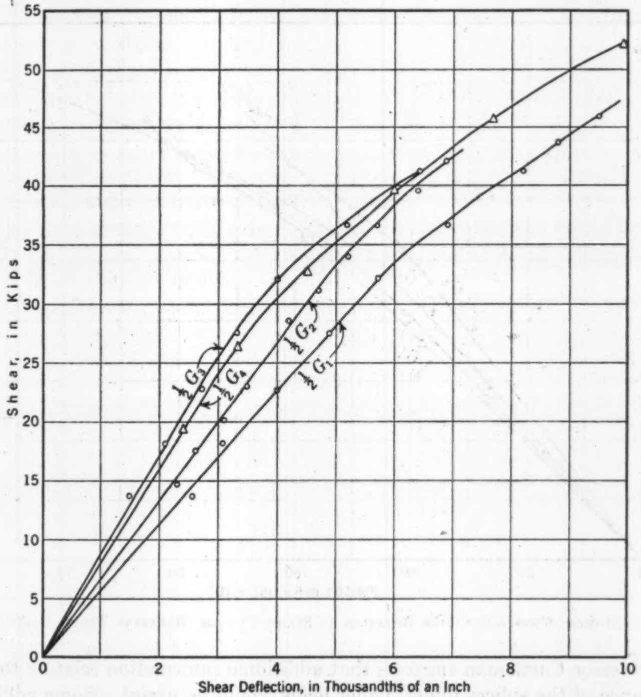

FIG. 16.—SHEAR-VERSUS-RELATIVE-SHEAR DISPLACEMENT CURVES (BREAKING TESTS, HALF-GIRDERS)

Professor Johnston has stated that the calculated stress at maximum load is very close to the weighted yield-point average if the net moment of inertia is used. However, it seems to the writers that, since failure of all of the girders was due to buckling of the compression flange, no particular relation exists between net moment of inertia and the failure load. The fact that very little is known about the structural action involved when a plate girder fails is ample proof that the problem warrants further study and tests. Professor Johnston is quite right in emphasizing the uncertainty as to the margin of safety in a plate girder, but the data reported in this paper were intended primarily to give information relating to the behavior of the splices and their effect on the structural behavior of the girder near the splices.

Professor Castleman has assumed that the top flanges of the girders were not braced laterally, since the writers did not mention the method of supporting the girders. Actually, the top flanges were supported laterally at a point near the end of each girder and the third-points of the span by steel angle frames attached to the supporting beams. With these supports, the flange appeared to remain straight until failure had occurred due to the local buckling action.

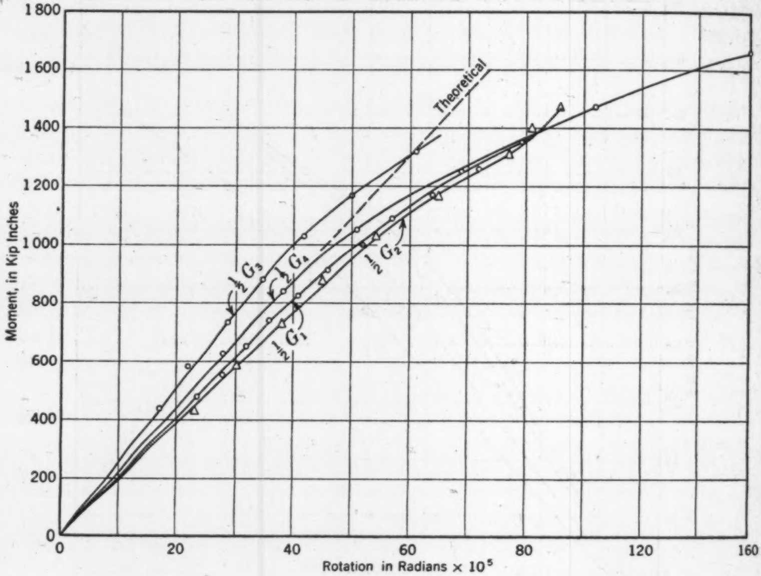

FIG. 17.—MOMENT-VERSUS-RELATIVE ROTATION AT SPLICE CURVES (BREAKING TESTS, HALF-GIRDERS)

Professor Castleman suggests that additional information relating to shear resistance of the splices under higher loads would be useful. Some additional data were obtained that may be helpful in this respect. Following the tests on the full-length girders, a 10-ft 5-in. length of girder containing splice 1 was cut from the end of each girder, and will be referred to as $\frac{1}{2}\,G_1$, $\frac{1}{2}\,G_2$, etc. The girders $\frac{1}{2}\,G_1$, $\frac{1}{2}\,G_2$, and $\frac{1}{2}\,G_3$ were tested to failure by the application of a single load at a point 69 in. from the end of the girder and 37 in. from the center line of splice 1. Girder $\frac{1}{2}\,G_4$ was loaded at a point 46 in. from the end of the girder and 14 in. from the center line of splice 1.

The girders failed by buckling of the compression flange at the load point. This failure, like that in the full-length girders, was caused by local buckling of the flange, due to the stresses caused by the moment, and by local stresses under the load. Although the splice was not placed at the point of maximum moment, it was subjected to higher shear stresses than in the tests of the full-length girders.

Strain measurements were taken to determine the shear-versus-relative-shear displacement and moment-versus-relative rotation. These values are shown in Figs. 16 and 17. The maximum loads and moments for these half-girders are shown in Table 5. The section modulus of $\frac{1}{2}\,G_4$ at the load point was only two thirds of that for the other girders, since the cover plate is not effective on $\frac{1}{2}\,G_4$. The action indicated in Figs. 16 and 17 is consistent with that shown for the full-length girders in Figs. 9 and 10.

TABLE 5.—MAXIMUM LOADS AND MOMENTS

Girder	FORCES, IN KIPS		Moments at load point, in kip-in.	Moment at splice, in kip-in.
	Load	Shear		
$\frac{1}{2}\,G_1$	104	47.7	3,210	1,530
$\frac{1}{2}\,G_2$	112	51.4	3,460	1,640
$\frac{1}{2}\,G_3$	105	48.2	3,260	1,540
$\frac{1}{2}\,G_4$	92	60.1	2,610	1,920

These tests have demonstrated that plate girder splices do not act in accordance with the assumptions made in designing them. The problem is complicated by the fact that the lengths of the splice plates have an effect which cannot be fully taken into account and by the fact that the rivets act in a manner which does not admit of exact mathematical analysis.

The writers are grateful to those who discussed this paper.

COMPACTION OF COHESIONLESS FOUNDATION SOILS BY EXPLOSIVES

BY A. K. B. LYMAN,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. REUBEN M. HAINES, R. G. HENNES, JOHN D. WATSON, PAUL BAUMANN, AND A. K. B. LYMAN.

SYNOPSIS

The method of compacting loose, cohesionless foundation soils in their natural state by detonating buried charges of explosives has been used successfully at Franklin Falls Dam, Denison Dam, and Almond Dam. The use of this method, as reported herein, is intended to draw attention to a new economical and efficient method of obtaining a satisfactory degree of compaction in cohesionless foundation materials. To employ this method successfully, the materials must be in a condition approaching complete saturation, and under such conditions, this method is widely applicable to all loose, cohesionless structural foundations. The results obtained in investigations to date (1941) indicate that in addition to increasing the degree of compaction of the materials, the horizontal permeability of stratified deposits is greatly reduced. Further investigations and tests are needed to determine the limits of compaction for specific materials and whether optimum results can be obtained in fully or partly saturated material.

INTRODUCTION

Franklin Falls Dam on the Pemigewasset River near Franklin, N. H., was designed for the control of floods on the Merrimack River. In their natural state at this site, there are deposits of loose, fine alluvial sand, especially in the river terraces of the foundation area of the embankment that constitutes a part of the project development. Extensive investigations disclosed that the stability of the embankment would be considerably increased if these loose sand deposits could be consolidated to reduce the possibility of their failure by liquefaction due to disturbance caused by earthquakes, demolitions, or blasting in the vicinity.[2] Estimates of cost were prepared for various compaction

methods, including that of driving piles and the use of large vibrators and tamping equipment to reduce the voids ratios of the loose terrace materials below critical values, as defined by Arthur Casagrande, Assoc. M. Am. Soc. C. E. Consideration was also given to the excavation of the loose materials and replacement by the same or other materials in a dense state by accepted compaction methods. The uniformly high cost of the treatments considered led the writer to investigate the feasibility of compacting the loose deposits by use of buried charges of explosives.

As a necessary prerequisite to the application of this method to compaction of loose soils it is necessary to consider: (*a*) Type of soil; (*b*) condition or degree of saturation of soil; and (*c*) depth of deposit. Although compaction by blasting was initially developed for the treatment of loose deposits of uniformly graded, slightly silty, fine to medium sands at Franklin Falls, subsequently sands containing a substantial percentage of silt have been successfully compacted at one other locality.

Saturation of the soil to be compacted, at least in the region of the explosive charges, is regarded as conducive to the best results. However, fairly effective compaction has been obtained in tests at the Denison (Tex.) Dam under conditions of partial saturation. The pore water probably acts initially as a tamping medium, thus facilitating the progression of the vibratory waves or shocks emanating from the charges. The explosion of buried charges induces a "liquefaction" of the soil mass, followed by an escape to the ground surface of excess pore water which acts as a lubricant to facilitate a rearrangement, in a more compact state, of the soil grains in the vicinity of, and overlying, the charge. Extensive explorations after blasting disclosed the absence of cavities which may have been created momentarily by blasting in the soil mass.

There are no apparent limitations to the depths of deposits that may be consolidated by means of explosives. On the contrary, deposits of sand at considerable depth may be compacted in this fashion, whereas they may not be readily accessible to other forms of treatment.

It is thought that where loose strata of sand greater than 30 ft thick are to be compacted, two or more tiers of small charges are to be preferred to one tier of large charges. For deposits less than 30 ft thick charges at depths, below the top surface of the mass to be compacted, of approximately two thirds of the thickness of the loose soil mass, will generally suffice.

The size and distribution of charges should be such as to shatter the soil mass thoroughly but not to the extent of creating permanent surface craters. A surface crust of impervious material inhibits the emission of the surplus pore water from the ground and must be disturbed, fractured, or removed. Following the dull thudding sound of the blast there is an upheaval of the ground surface in the range of influence, a fracturing of the surface, and the escape of gas and water for periods of from minutes to hours from crater-like openings similar to sand boils which appear on the surface. The primary surface settlement immediately follows the initial upheaval, and continued settlement is apparent for a few minutes. No doubt settlement continues for some time as part of the adjustment of the soil mass accompanying the continuing expulsion of surplus pore water.

The lateral distribution of charges should be based on results obtained from a series of single shots. A horizontal grid spacing of charges, 20 ft on centers, for the initial coverage, with an orderly interspersion of four subsequent coverages in the space intervals between prior coverages, proved satisfactory at Franklin Falls.

The degree of compaction obtained by blasting can be demonstrated by tests of undisturbed samples taken before and after the compaction operation. Undisturbed sampling below the ground-water table, although requiring expensive test pits, is necessary if the results are to be evaluated accurately. Observation of ground-surface settlement by means of stakes or anchored plates permits a generalized interpretation of the effectiveness of the blasting method. Moreover, such observations indicate the settlement for each blasting coverage and, hence, are a key to the number of coverages required.

The method of compacting loose, cohesionless foundation materials by means of buried explosive charges has been applied successfully to the river terraces which form a large part of the embankment foundation area at Franklin Falls Dam. Tests have also been conducted at Denison Dam in Texas and at the site of Almond Dam in western New York State.

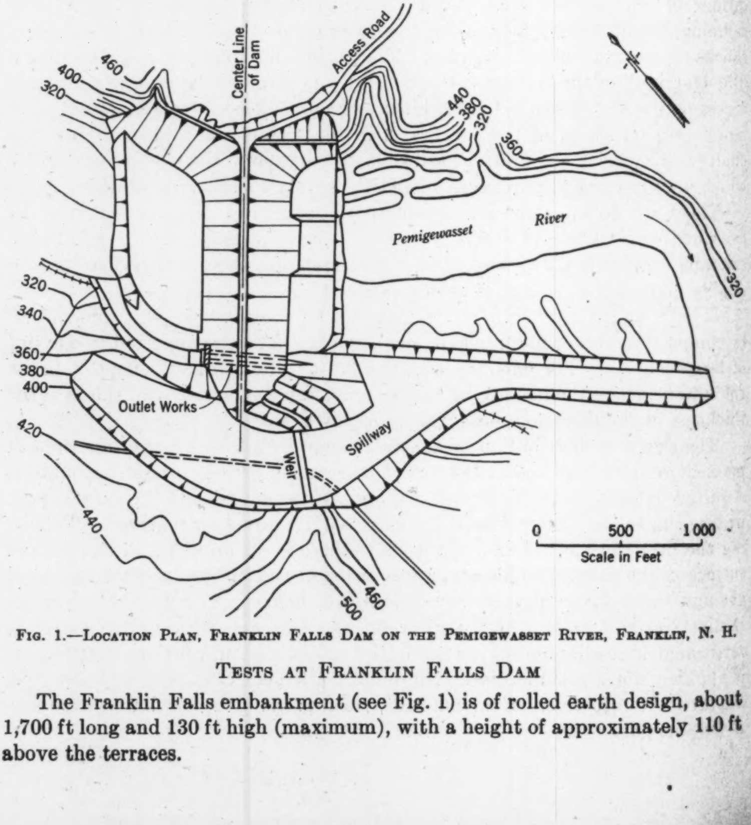

Fig. 1.—Location Plan, Franklin Falls Dam on the Pemigewasset River, Franklin, N. H.

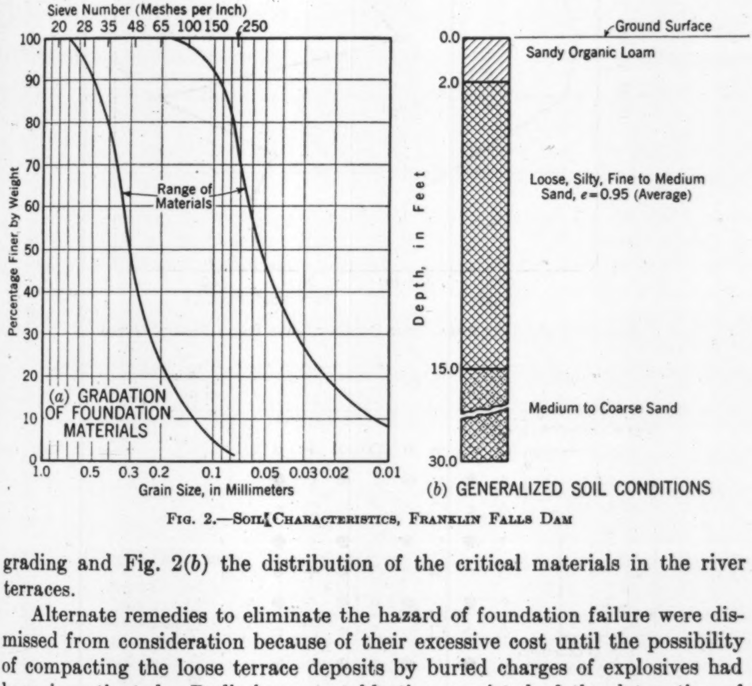
Tests at Franklin Falls Dam

The Franklin Falls embankment (see Fig. 1) is of rolled earth design, about 1,700 ft long and 130 ft high (maximum), with a height of approximately 110 ft above the terraces.

The embankment foundation area consists in part of two overbank flood plains or terraces, each about 400 ft wide, of loose, fine-to-medium, alluvially-deposited sands extending to depths of from 15 to 30 ft. Below this stratum are stable coarse sands and gravels. As construction of the dam proceeds the loose, cohesionless materials will consolidate slightly, but not sufficiently to reduce the fine materials below their critical voids ratios for the loads to be imposed. Apprehension was felt that these deposits might suddenly "liquefy" and flow from beneath the embankment due to disturbance caused by earthquakes, slides, settlements, or vibrations. Fig. 2(*a*) indicates the range of grading and Fig. 2(*b*) the distribution of the critical materials in the river terraces.



(*b*) GENERALIZED SOIL CONDITIONS

FIG. 2.—SOIL CHARACTERISTICS, FRANKLIN FALLS DAM

Alternate remedies to eliminate the hazard of foundation failure were dismissed from consideration because of their excessive cost until the possibility of compacting the loose terrace deposits by buried charges of explosives had been investigated. Preliminary test blasting consisted of the detonation of individual charges of dynamite ranging from 2 lb to 8 lb at depths of 10 to 16 ft below the ground surface; optimum consolidating effect was produced by charges of 8 lb of 60% dynamite at a depth of 15 ft below the ground surface.

A test area was next blasted with twenty-one charges at depths of 15 ft distributed into four coverages with final grid intervals of 10 ft. An average ground-surface settlement of the test area of 1.25 ft resulted. Tests of undisturbed soil samples taken from a test pit excavated to a depth of 8 ft in the center of the blasted area yielded the results indicated in Fig. 3. It is estimated that the average voids ratio before blasting was 1.0 and the degree of compaction 36%.

To confirm these results and further develop the method, a second test area, with five blasting coverages (see Fig. 4), resulted in an average ground-surface settlement of 2.0 ft, the compaction being effective over an estimated depth of 20 ft. Pits were excavated before (Pit 610) and after (Pit 611) blasting. Tests of undisturbed soil samples indicate changes in voids ratio and degree of compaction as plotted in Fig. 5. No evidence of cavities was revealed by the test pits excavated after the blasting operations. A total of six soil samples taken at each elevation indicated a fairly uniform degree of compaction laterally at each depth.

Permeability is reduced substantially by the compaction operations and is attributable to two causes: First, the reduction in void spaces between soil grains; and second, the breaking up of lensing and stratification of the natural deposits. The relative magnitude of these two effects is shown in Fig. 6. Field pumping tests before and after compaction operations from identical well

point systems around test pits 610 and 611 resulted in quantities of flow of 400 gal per min and 75 gal per min, respectively. Laboratory tests indicate that the reduction in voids ratio would account for only 45 gal per min, and the remainder of the reduction of 280 gal per min is attributed to the breaking up of lensing and stratification which indicates the importance of altering this characteristic of highly permeable soil deposits.

As a result of these tests it was concluded that the loose sand terraces could be compacted satisfactorily by blasting methods. Each of the terraces, measuring approximately 400 ft by 850 ft, was compacted by using a total of 12,000 explosive charges. On the west terrace the average ground-surface settlement was 2.0 ft in a depth of 20 ft of loose materials. On the east terrace where the loose materials extended to an average depth of 25 ft, the settlement was greater, averaging about 2.5 ft.

Fig. 8.—Jetting Drill for 8-Lb Charges of Dynamite

Fig. 9.—Jetting Crew Using Drill and Tripod

Excavation of trenches in the compacted terraces for the foundation drains beneath the embankment afforded opportunity for extensive undisturbed sampling. The fifty-seven samples tested indicate an average voids ratio of

0.780 for the compacted materials in the west terrace and 0.736 in the east terrace, with respective degrees of compaction of 45.7% and 56% for the west and east terraces.

The breaking up of lenses and stratifications in the Franklin Falls terraces by blasting results in a slight mixture of the material and is important as a means of reducing permeability. Undisturbed samples (after blasting) of sufficient size for tri-axial testing present such a wide variation of grading from point to point that isolation of the more critical uniformly fine materials for testing was found to be infeasible. The results of the blasting compaction at Franklin Falls must be evaluated in part by judgment and experience in critical density testing of fine cohesionless materials similar to those which are of concern in the terrace foundations. The uniform, fine, cohesionless embankment materials at Franklin Falls (which are similar in character and grading to the critical, fine alluvial sands in the terraces) have been tested extensively; and, for the design loadings, a critical voids ratio of 0.67 has been determined. Although not subject to strict correlation, the voids ratios in the terraces, after blasting (with values as low as 0.656 but generally ranging from 0.72 to 0.80), may be favorably compared with those of the mechanically compacted embankment. It is manifest that a comparison of these voids ratios provides considerable assurance that dangers of liquefaction have been reduced greatly.

Decreases in thickness of the loose sand deposits, from 2 to 2.5 ft in a depth of 20 ft, and reduction of the average voids ratio in the natural state of approximately 0.95 to the average values after blasting, previously cited, are indicative that the major settlement hazard has been eliminated. The berms at the toe of the embankment slopes, shown in Fig. 7, serve to contain the foundation; and the deep downstream foundation drain trench, which is backfilled with gravel, provides a ready path for the escape of surplus pore water should the terraces be subjected to vibratory stress. The section of the embankment in the river channel has its foundation approximately 20 ft below the embankment on the terraces, thus virtually enclosing the critical terrace foundations. These facts all provide assurance that adjustments in the terrace foundations, under stress conditions of reasonable expectancy, will be of a purely local nature and that the possibility of "flow" of the terrace foundations is quite remote.

The cost of compacting the Franklin Falls terrace foundation is approximately \$35,000, or \$0.09 per yd, for the material compacted. This compares with a minimum estimated cost of \$125,000 for treatment by other methods. The equipment used at Franklin Falls to jet the blasting charges in place is shown in Figs. 8 and 9.

Tests at Denison Dam, Texas

At the Denison Dam Site, on the Red River near Denison (see Fig. 10), the river bed is about 900 ft wide and consists of loose deposits of sand and silt, with some intermixed clay extending to depths of 30 ft. During low-water periods the river occupies only a small part of the river bed. Preliminary compaction tests in the South River area, consisting of single charges of dynamite, showed that charges of 16 lb at depths of 16 ft would yield the best results.

A test area 250 ft by 180 ft (North River test area, Fig. 10) was then blasted using seventy-three charges exploded in five individual blasts. An average surface settlement of 0.68 ft was obtained for the area. However, some of this settlement represents a migration of material toward the unconfined river bank.

FIG. 10.—RIVER AND LOWER TERRACE AREAS, SITE OF DENISON DAM, IN TEXAS

Tests of undisturbed samples before and after blasting gave the voids-ratio decreases indicated in Fig. 11(*a*).

A second test area on the Oklahoma Terrace (left bank) of the dam where loose, cohesionless materials existed in the embankment foundation was then blasted. The ground-water table in this vicinity is approximately 22 ft below the surface, and pumping and ponding of water were necessary to produce the saturated condition requisite for consolidation blasting. An area 145 ft by 200 ft was enclosed in a small dike and pumping operations were continued with few interruptions for eighteen days with the result that the ground-water table was raised to within 10 ft of the surface; the material between the ground surface and the artificial water table was well moistened. Of the two blasts in the Oklahoma Terrace the first consisted of 312 lb of dynamite split into fifty-one charges placed in three tiers at depths of 5, 10, and 15 ft. The charges in each tier were placed in a pattern of squares 40 ft on a side. Each tier was oriented so that the charges were spaced midway between the charges of the other tiers in plan. The lower tier of sixteen charges of 12 lb of 60% dynamite was set off with instantaneous caps; the middle tier of fifteen charges of 6 lb of 40% dynamite was set off with first-delay caps; and the upper tier of twenty charges of 1.5 lb of 40% dynamite was set off with second-delay caps. The second blast consisted of 414 lb of dynamite divided into fifty-one charges placed in two tiers at depths of 10 and 15 ft.

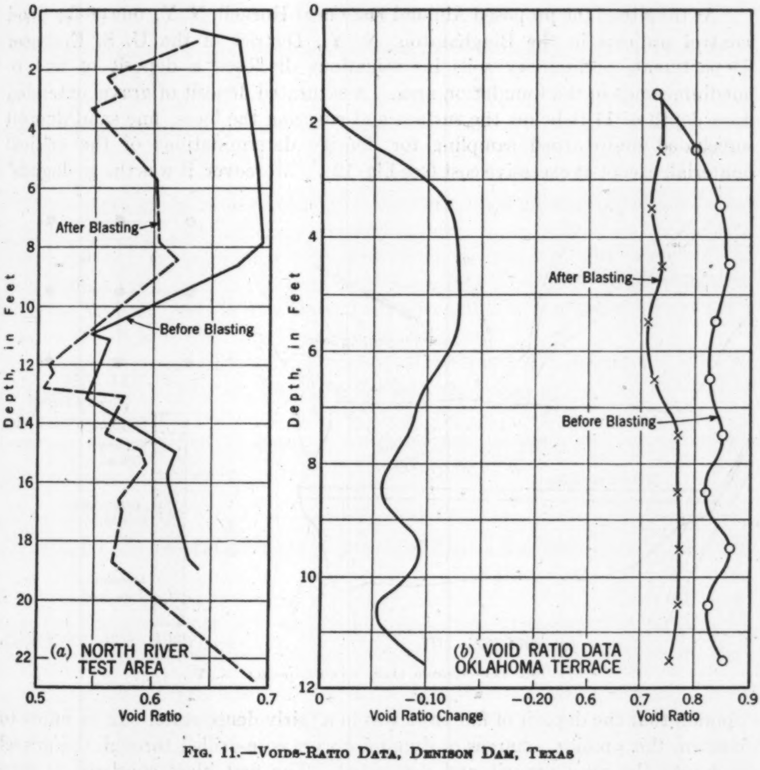

FIG. 11.—VOIDS-RATIO DATA, DENISON DAM, TEXAS

Average settlements of 0.27 ft for the first blast and 0.22 ft for the second blast, or a total of 0.49 ft, were observed. Two test pits, one before blasting and one after blasting, were excavated to a depth of 11.5 ft for obtaining laboratory samples for voids-ratio determinations. A voids-ratio decrease of approximately 0.09 resulted from the two blasts, the major compaction being between the depths of 2.5 ft and 7 ft in the zone where the material was well moistened rather than fully saturated (see Fig. 11(*b*)). The report[3] of the tests at Denison states:

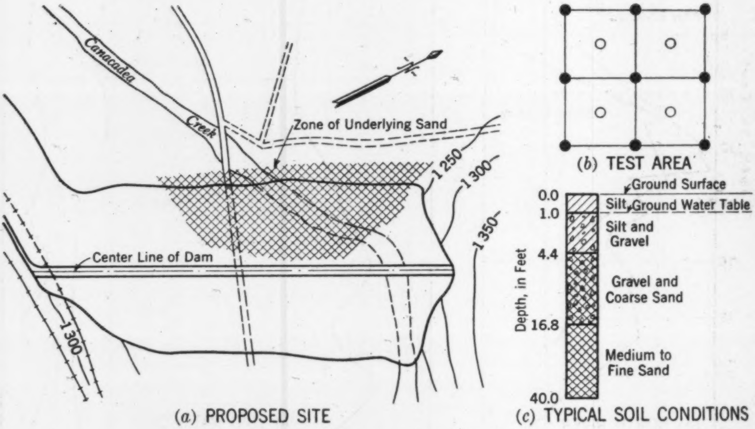
---

[3] "Inspection Report—Dynamite Compaction Tests, Denison Dam and Reservoir," U. S. Engr. Office Denison, Tex., dated December 7, 1939 (unpublished).

> "Compaction can be obtained by blasting. Results in the River Area show that the critical voids ratio of 0.6 can be very closely approached and that with an average surface settlement of less than one foot. On the Oklahoma Terrace experiments were not carried far enough to learn if the critical voids ratio could be attained, but it is evident that the voids ratio can be decreased considerably even without complete saturation."

Tests at Almond Dam, Hornell, N. Y.

At the site of the proposed Almond Dam near Hornell, N. Y., one of the flood control projects in the Binghamton, N. Y., District of the U. S. Engineer Department, preliminary soils investigations disclosed a deposit of fine to medium sands in the foundation area. A saturated deposit of gravel extended to a depth of 17 ft below the surface and covering the loose, fine sand deposit precluded undisturbed sampling for density determinations of the critical material, except at excessive cost (see Fig. 12). Moreover, it was the geologists' opinion that the deposit of fine sand was in a fairly dense state. In an effort to confirm this opinion, charges of dynamite were core-drilled through the gravel and into the sand deposit and detonated. The first blast consisted of nine charges of 50 lb each of 60% dynamite. These were placed in a pattern of squares 50 ft on a side, all charges being at a depth of 40 ft below the surface. The second blast consisted of four charges, also 50 lb each in size and at a depth of 40 ft below the surface. The lateral spacing of these four holes was intermediate to the initial nine holes. The third and fourth blasts consisted of reloading and firing the preceding nine-hole and four-hole blasts, respectively. However, the size of each charge was decreased to 20 lb of explosive and the depths were reduced to 30 ft below the surface.



(*b*) TEST AREA

(*a*) PROPOSED SITE

(*c*) TYPICAL SOIL CONDITIONS

Fig. 12.—Almond Dam, Near Hornell, N. Y.

As a result of the four blasts the ground surface of the test area settled an average of 0.1 ft. This was such a slight settlement that it was concluded that the fine sand deposit was initially in a fairly dense state of deposition and no compaction or other treatment would be necessary. It must be emphasized, however, that until more investigations have been conducted in connection with this new method, the failure of an area to settle upon blasting cannot be regarded as conclusive evidence that the material is below the critical voids ratio or that it is stable under all possible stress conditions.

SUMMARY

The method of compacting cohesionless foundation soils by means of explosives was developed and used in the embankment foundation at Franklin Falls Dam. Considerable economy was effected over any previously available methods of compaction, such as vibrators or pile driving, and also over the process of excavating the unsuitable material and recompacting with suitable materials.

The method, in brief, consists of the detonation of charges of explosives spaced laterally and vertically throughout the loose soil mass. Successive coverages of the same area give additional compaction, but the limits of compaction for a specific material by this method have not been investigated. Neither have the tests to date been extensive enough to show whether optimum results are obtained in fully or partly saturated soil.

It can be stated definitely, however, that the present indications are that the method is widely applicable to loose, cohesionless structural foundations provided the materials are substantially saturated prior to blasting. In addition to increasing the degree of compaction of the materials, the horizontal permeability of stratified deposits is greatly reduced.

ACKNOWLEDGMENT

The investigations and tests at Franklin Falls Dam were conducted under the supervision of the writer. Investigations at Denison Dam were conducted under the direction of Maj. Lucius D. Clay, M. Am. Soc. C. E., district engineer, Dension District of the U. S. Engineer Department. Investigations at Almond Dam were conducted under the direction of Lt.-Col. George J. Nold, M. Am. Soc. C. E., district engineer, Binghamton District of the U. S. Engineer Department.

DISCUSSION

Reuben M. Haines,[4] **Assoc. M. Am. Soc. C. E.**—The initial tests and first actual application of the method of compacting loose, cohesionless foundation soils by detonation of buried charges of explosives are described in this paper. Colonel Lyman is to be highly commended for conducting the investigations, and for his presentation of data, since this method of compaction may provide an economical and practical solution to produce a suitable foundation for many structures. Before the limitations of the method are known, additional information and data will need to be obtained by future field and laboratory investigations. Since the author has proved that the method is practicable for certain conditions, it is believed that additional information will become available in the near future. The costs of making preliminary investigations where the method might be used would appear to be inexpensive. Such investigations should be made to determine if settlement can be obtained for the particular soil deposit and to determine the spacing, order, and size of charges that would give the most compaction. It appears that the further development of the method is highly desirable. For certain soil conditions, it may be possible that the use of well points to remove excess water after detonation, or the loading of the area, will produce greater compaction.

This method of compaction can be used only for soil deposits in which a new and denser soil structure will be formed if the material is completely disturbed. The compaction that can be obtained is limited and depends upon the type of soil particles, type of soil structure, the initial density, the permeability, the drainage conditions, the stress conditions, and the degree of saturation. The detonation of the buried charges in a saturated loose deposit produces a liquid or partly liquid mass by destroying the soil structure. The particles of soil settle to form a new structure as the excess moisture seeps from the mass. The rate and quantity of seepage probably affect the degree of compaction obtained after the detonation of a charge. After the excess moisture has escaped and the new soil structure formed, the detonation of another charge produces additional compaction; however, the data of the tests at Denison Dam show that there will be less change in density than by the detonation of the previous charge. The number of coverages to produce optimum compaction can be determined only by field tests. It would be interesting if Colonel Lyman, in the closing discussion, would present any additional available data that may indicate the change in density by the detonation of each successive charge. The writer believes that the inertia and tamping actions produced at the time of detonation have little effect upon the compaction of saturated materials; however, if the soil deposit is only partly saturated, these actions may be primary causes of the compaction of the soil particles as rearranged by resettlement. The writer believes that only a minor degree of compaction can be obtained by this method unless there is sufficient moisture to produce partial liquefaction when the soil structure is shattered.

---

[4] Engr., Corps of Engrs., U. S. Army, Washington, D. C.

The development of the method may lead to many practicable uses. During the construction of many earth dams, the current procedure is to dewater the channel areas and place rolled-fill materials. Investigations may develop this method so that cohesionless material may be placed and satisfactorily compacted in the channel areas of some projects without the construction of cofferdams and dewatering of the area. Until more is known about the stress-strain relations of cohesionless materials when subjected to disturbances, and until the critical void ratios for various stress conditions can be determined, it will not be known if this method can be used to produce a density below the critical void ratio for any imposed loads of appreciable magnitude. Any foundation, however, would have a satisfactory density to insure against liquefaction if this method is used after the stresses of the imposed load are produced in the deposit; but this procedure may be very expensive for large earth-dam projects. The method may be economical and practicable for many earth-dam projects, as in the case of the Franklin Falls Dam where only a moderate degree of compaction of the foundation deposits on the terraces was required due to foundation and design features.

R. G. HENNES,[5] ASSOC. M. AM. SOC. C. E.—Many engineers have emphasized the importance of making generally available the results of experience with foundations and earthwork if the principles of soil mechanics are to be developed and utilized to best advantage. As a significant contribution to this field, the present paper should be most welcome. The value of such contributions is not fully exploited except by discussion, which preferably should spring from a background of comparable experience in the field. Description of new construction methods is unavoidably handicapped by the absence of parallel experience upon which adequate discussion could be based. It is to be hoped, therefore, that the author's closure of the present paper will be made the vehicle for presenting further information on this new method of compaction for the use of the profession.

Especially appreciated would be any additional test data that may be available which would assist the engineer in applying this method to other projects without unnecessary duplication of effort. In any such application the main thing to be determined is the size and distribution of charges. The variables upon which the layout depends are stated to be the type of soil, its degree of saturation, and the depth of the deposit. Fortunately, the problem is somewhat limited by the practical consideration that only in loose sandy deposits does the critical void ratio tend to be a controlling factor. Theory would seem to approve the author's conclusion that best results are to be expected when the soil is saturated; for the very danger associated with the concept of a critical void ratio is the "liquefaction" produced by the excess of water in the voids. The Denison tests suggest that the effect of saturation is less simple, and point to the need for further research in this field. The effect of depth is something that can be disclosed only by experiment, and it is here that the paper comes closest to permitting at least tentative general conclusions. It would be helpful if the author's closure considered this matter at greater length. Both at Franklin Falls and at Denison best results appear to have been obtained by placing charges at a depth of 15 ft, but in neither case is it clear how deep the effect was felt, and it would be of interest to learn what evidence led to the conclusion "that where loose strata of sand greater than 30 ft thick are to be compacted, two or more tiers of small charges are to be preferred to one tier of large charges" (see "Introduction").

---

[5] Associate Prof., Civ. Eng., Univ. of Washington, Seattle, Wash.

It is not the thought of the writer that any amount of discussion can obviate the need for preliminary tests on each individual project, but rather that each new investigation should be shaped by the fullest comprehension of what has already been accomplished.

John D. Watson,[6] **Assoc. M. Am. Soc. C. E.**—The results presented in this paper show positively that the method is economical and that loose cohesionless soils can be made much denser, and also considerably less permeable. Colonel Lyman is to be commended most heartily for originating and developing a method of foundation improvement that will be of great value to foundation engineers throughout the world.

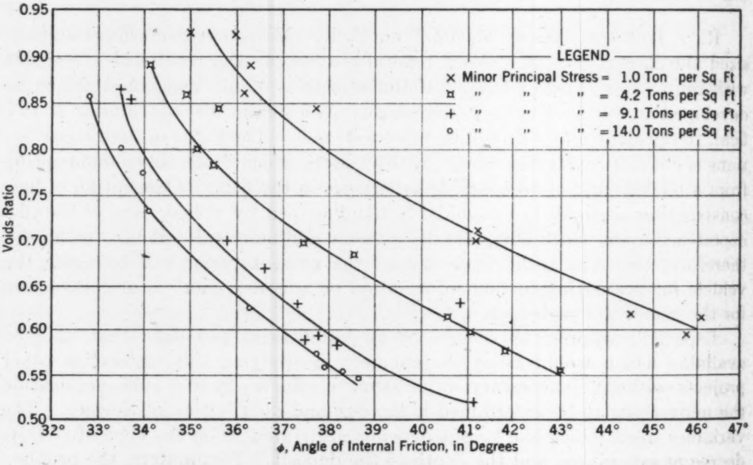


Fig. 13.—Empirical Relationship Between Voids Ratio and Angle of Internal Friction for Franklin Falls Sand

Although the author states (see "Introduction") "that the stability of the embankment would be considerably increased if these loose sand deposits could be consolidated to reduce the possibility of their failure by liquefaction * * *," he did not take the opportunity to point out the concomitant advantage of the greater resistance to rupture that these soils would have by reason of the higher density. In 1938, when the writer was serving as research fellow in soil mechanics for the Graduate School of Engineering at Harvard University, in Cambridge, Mass., he made many tri-axial compression tests on samples of a fine cohesionless sand from the Franklin Falls Dam site.

---

[6] Asst. Prof., Civ. Eng., College of Eng., Duke Univ., Durham, N. C.

The samples for these tests were prepared with a wide range of voids ratio (0.925 to 0.52, comparable to a unit dry weight of 88 lb per cu ft to 112 lb per cu ft), and the tests were made with a surrounding hydrostatic pressure ranging from 1.0 to 14.0 tons per sq ft. The results of these tests are shown in Fig. 13. For the same minor principal stress (hydrostatic pressure), the angle of internal friction is inversely proportional to the voids ratio. However, the amount of the variation changed with the intensity of the minor principal stress. When the minor principal stress was low, the increase in the angle of internal friction with a decrease in the voids ratio was greater than when the minor principal stress was high. The following explanation for this fact has been offered tentatively: When the minor principal stress is low, rupture occurs by one grain of sand sliding over another, and the interlocking effect of the grains is considerable. When the minor principal stress (and the major principal stress as well) is high, then many grains in the plane of failure break apart and the interlocking effect is less pronounced. Similar variations in the angle of internal friction with changes in density and minor principal stress were found for other sands.

Karl Terzaghi, M. Am. Soc. C. E., has pointed out many times that the strength of a cohesionless soil foundation does not depend upon the first, but rather upon the fourth, power of tan $\left(45 + \frac{\phi}{2}\right)$, in which ϕ is the angle of internal friction. Hence, when the angle of internal friction of any sand is raised by compaction from 34° to 38°, the resistance to rupture of this soil beneath a foundation load increases not just 9%, but rather it increases 42%; and, if the angle of internal friction could be raised from 34° to 46°, the strength of the material against rupture by a foundation load would increase 200%. Although the possibility of loading a foundation of cohesionless soil to the point of rupture by means of an embankment is admittedly remote, nevertheless the large increase in the strength of such soils through compaction is quite pertinent for other types of foundation loading and for the stability of embankments as well.

PAUL BAUMANN,[7] M. AM. SOC. C. E.—Presented with military brevity and precision, this paper is very timely indeed and should prove to be of distinct significance in view of many floating dams that have been built or are proposed to be built in connection with the national flood control program.

The consolidation of granular foundation materials by means of shock or vibration, as a result of blasting, stands in contradistinction to the chemical methods of solidification of similar materials. In principle, the first method consists of rocking the particles into closer contact, whereas in the second case the particles remain undisturbed and the voids between them are filled partly or completely by a suitable combination of liquid chemicals. Both methods have at least one feature in common—namely, the difficulty of access and inspection as well as sampling to ascertain the results of the treatment. Hence, the control of the stabilization of foundations of this character is definitely at variance with the control of the stabilization by means of compaction of embankments above the ground surface. The latter are ordinarily built in relatively thin layers, offering ready access to testing at all times.

---

[7] Senior Asst. Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

The blasting technique, as described by the author, resembles certain methods of demolishing mine tunnels or underground communications of various types well known in military engineering, particularly in connection with field fortifications. One of the many tasks of the sapper is the demolition of such enemy underground passages without appreciable disturbance of the ground surface—that is, especially without the formation of a crater or a "mole hill." This is accomplished by the so-called squash mines that have a striking resemblance to the type of mines described in the paper.

Contrary to the normal crater charge with a sphere of influence touching the ground surface as shown in Fig. 14 by the solid circle, the sphere of influence of the squash mine is much smaller, possibly as indicated by the dotted circle. Expressed in kilograms and meters for the weight W of the dynamite charge and the radius R of the sphere of influence, respectively, the simple relation

$$W = c \times R^3 \qquad (1)$$

exists, in which c is a coefficient that approaches unity for a 60% dynamite placed in fully tamped blast holes in medium-fine sand.

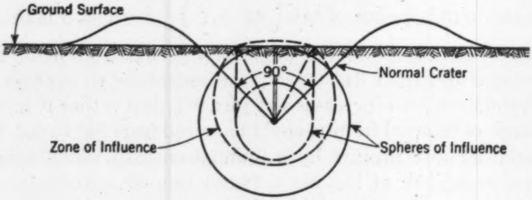

FIG. 14

According to the author's information, best results were obtained, at least in one location, if a charge of 8 lb of dynamite was used 15 ft below the ground surface. For the normal crater charge that would result in a 90° cone, more or less, the formula would call for approximately 200 lb of dynamite. Hence, the charge actually used was one twenty-fifth of the normal crater charge. Ordinary squash mines would probably range between one tenth and one fifteenth of the normal crater charge, depending on the character of works subject to demolition. Therefore, they would receive roughly double the charge as used for best compaction. This means that test pits within the blast area, if adequately timbered, would not be subject to destruction from compaction blasts unless they were located within the zone of influence—that is, in this case, within about 5 ft of the charge. Hence, there appears to be no reason why, with a relatively small additional expense, a more rigid control of the process could not be attained.

It is to be expected that compaction by blasting would result in somewhat erratic degrees of compaction. This is particularly notable in the data shown for the Denison Dam where the foundation material within the range of blasting was not saturated. A saturated condition is undoubtedly very desirable for more uniform propagation of the pressure waves, as the author clearly states. In studying Fig. 11, and particularly the part applying to the North River test area, it is significant that, at about 13 ft of depth, the density of the material was greater before blasting and that below some 18 ft of depth the trend of the curve showing the conditions after blasting is in the direction of diminishing density with increasing depth. In this connection, the author's emphasis of the need for further investigation before definite conclusions can be drawn from results so far obtained is believed to be well supported.

The writer had occasion to make studies and to direct tests on the solidification or petrifaction of granular material by means of chemical methods. Although this was a number of years ago and prices of chemicals may have changed considerably in the meantime, it is the writer's conviction that any one of the feasible chemical treatments to accomplish what apparently was accomplished by means of blasting would have been far more expensive than the latter method.

A. K. B. LYMAN,[8] M. AM. SOC. C. E.—The tests for developing the method of compaction by detonating buried charges of explosives were unique and, therefore, no additional data have been presented in the discussions. They have been mainly limited to descriptions of the compaction phenomenon, the limitations and possible applications of the method, and a request for additional information. The purpose of the tests was to prove that, for certain conditions, foundation soils could be compacted economically by detonating buried charges of explosives. As Mr. Haines states, the limitations of the method will not be known until additional information and data are obtained by future field and laboratory tests. The writer believes that the tests conducted to date must be considered as preliminary and, in the future, the procedures for various conditions may be radically different from the one used at the Franklin Falls Dam site. Mr. Haines suggests that "For certain soil conditions, it may be possible that the use of well points to remove excess water after detonation, or the loading of the area, will produce greater compaction." A preliminary test was made at the Franklin Falls Dam site, using well points. The results of the test indicated that no appreciable increase in compaction could be obtained by using well points at this particular site. However, the writer fully agrees that various ideas should be used in tests for various conditions. It is quite probable that greater compaction could be obtained by using well points, particularly if compaction is desired at a greater depth, or the soil is less permeable, than at the Franklin Falls Dam site.

Mr. Haines believes that data which indicated the settlement due to each blast may be of interest. Such data were obtained during the compaction in the test areas at the Franklin Falls site, but the writer regrets that they are not available for publication. In general, at the Franklin Falls site, approximately two thirds of the settlement was obtained during the first two blasts.

The writer is unable to present, as suggested by Professor Hennes, any additional data that would assist the engineer in applying the compaction method to other projects without making complete tests. Professor Hennes has questioned the writer's thought "that where loose strata of sand greater than 30 ft thick are to be compacted, two or more tiers of small charges are to be preferred to one tier of large charges." Professor Hennes has failed to note that this is not a definite conclusion made by the writer. Based on a study of the phenomenon that occurs and the results of the tests, the writer believes that more uniform and satisfactory results can be obtained with dispersed small charges of explosives in place of one large charge. However, future investigations may show that the present belief of the writer is not valid.

Professor Watson has discussed the effect of the increase of density upon the angle of internal friction of fine cohesionless sand. Although the initial tests were made with the view in mind to reduce the density to below the critical voids ratio, the compaction method is equally applicable for increasing the density of foundation soils for the purpose of increasing the angle of internal friction, which is the critical factor in design for some structures.

Mr. Baumann emphasizes that the control of compaction by the method of detonating buried explosives cannot be as rigid as the method used to compact embankments. The writer believes that as careful a control as possible should be applied when a new method is being developed for the purpose of collecting data. However, after the method is developed beyond the research stage, the amount of control required depends upon the aspects of design and the effect that variations have upon the stability of the structure. In the case of the Franklin Falls Dam foundation, it is believed that ample investigations were conducted prior to and after compaction to insure that the method produced satisfactory results.

OPERATION EXPERIENCES, TYGART RESERVOIR

BY ROBERT M. MORRIS,[1] ESQ., AND THOMAS L. REILLY,[2] ESQ.

WITH DISCUSSION BY MESSRS. NICHOLLS W. BOWDEN, AND EDGAR E. FOSTER.

SYNOPSIS

Some of the problems involved in the operation of a large flood-control and water-supply project are reported in this paper. The writers demonstrate how effectively the Tygart Dam can perform the functions for which it was planned. For example, the effect of the reservoir in reducing flood crests at downstream points is demonstrated. The accuracy of these estimates is dependent on the method of flood routing and the thoroughness with which it is consummated. The elements involved in routing these floods are described only briefly because a complex problem of this type would require a separate paper for complete presentation.

INTRODUCTION

At the junction of the Monongahela and Allegheny rivers, in Pennsylvania, lies Pittsburgh, the steel city, favored by nature with bounteous coal supplies and three broad rivers for its transportation. Nature can be exacting for its favors, however. Records indicate that almost annually since the eighteenth century flood waters rolling down from the western slopes of the Appalachian Mountains have inundated some parts of the expanding city. At the time of the 1907 flood, when Pittsburgh had grown to be the steel center of the world, the valleys of the Allegheny and Monongahela rivers were lined with industrial developments. The low-lying "Triangle" at the junction of the two rivers was the crowded business center of this great industrial district. The flood of 1907, reaching then unprecedented heights, took a terrible toll in lives and property damage and awakened the citizenry to the realization that, since their city had been built practically in the flood plain of the rivers, some means must be found to check the annual flood menace.

The Pittsburgh Flood Commission, formed after the 1907 flood, made a detailed study of methods of flood control and published a complete report.[3]

NOTE.—Published in April, 1941, *Proceedings*.

Fig. 1.—Location Map, Tygart Dam

Later surveys and studies were made by the United States Army Engineers. A complete plan for a ten-reservoir system for flood control in the Upper Ohio Basin was developed by the Army Engineers; and finally, in 1934, funds were appropriated by the federal government for the first unit in this system, a dam on the Tygart River, one of the main tributaries to the Monongahela. The latter river is one of the world's greatest industrial waterways, linking the bituminous coal fields of Pennsylvania and West Virginia with the steel mills and other industries of the Pittsburgh District. Since navigation on this stream was hampered periodically by low water in the dry summer and autumn months, this dam on the Tygart River was designed for the dual purpose of flood control and water supply.

The Tygart Dam and Reservoir, constructed and operated by the U. S. Army Engineers, have been in service since January, 1938. Following the great record-breaking flood of March, 1936, which caused an estimated monetary loss of $178,674,000 and heavy loss of life in the Ohio River basin above Wheeling, W. Va., money was appropriated by Congress for the extension of the reservoir system and four other units are now (1941) under construction. This paper purports to discuss some of the problems involved in the operation of a large flood-control and water-supply project and to demonstrate how effectively the Tygart Dam can perform the functions for which it was planned.

The dam is on the Tygart River in Taylor County, West Virginia. It lies just two miles by stream above the City of Grafton and 27 miles above Fairmont, W. Va., where the Tygart and the West Fork rivers join to form the Monongahela River. This latter river is canalized over its entire length of 128 miles, and from its mouth at Pittsburgh (where with the Allegheny River

FIG. 2.—VIEW OF TYGART DAM

it unites to form the Ohio River) to its source at Fairmont there are thirteen navigation locks and dams. The tributary drainage area of the Tygart Dam is 1,183 sq miles. This is 16.1% of the total Monongahela Basin (drainage area, 7,384 sq miles) and 6.2% of the combined drainage area of 19,117 sq miles of the Monongahela and Allegheny rivers at Pittsburgh.

This paper deals primarily with the operation of the reservoir rather than design or construction of the dam and only a brief description of the structure is presented herein for the purpose of clearness in explaining methods of operation.

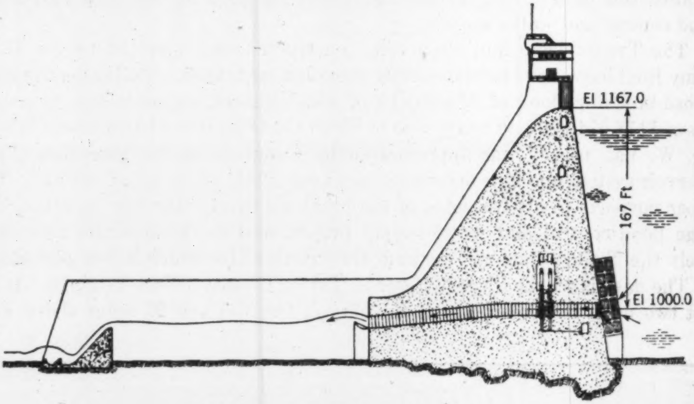

FIG. 3.—SPILLWAY SECTION, TYGART DAM

The dam is of the concrete gravity type, 1,880 ft long, and rises about 230 ft above bedrock. The spillway section, at about the middle of the dam, is 489 ft long and is flanked by bulkhead sections 23 ft higher than the spillway crest. The outlet works consist of eight conduits 5 ft 8 in. by 10 ft, each controlled by two, vertical, hydraulically operated, steel slide gates and two, 48-in., internal, differential, needle valves for low-water regulations. A cushion pool is provided below the main dam for the dissipation of the kinetic energy of discharge through the outlet works and over the spillway. Fig. 1 shows the location of the dam; a view of the completed structure is shown in Fig. 2; and a cross-sectional drawing is given in Fig. 3. The cost of the completed project, including railroad relocation, was about $18,000,000.

GENERAL FEATURES OF OPERATION

Reservoir Capacity.—The size of a flood-control reservoir is governed both by the economic feasibility and the hydrologic potentialities of the project. The dam should be built to a height necessary to produce a reservoir of sufficient capacity to provide a reasonable degree of control over floods similar to those of past record and over theoretical floods that may possibly occur in the future. Where storage for low-water control must also be considered, as in the case of the Tygart Reservoir, this feature becomes doubly important. The height of the dam and attendant reservoir capacity are also limited by the point at which the cost of the completed project, converted to annual charges, approaches the monetary benefits that will result from its operation. Exhaustive hydrologic and economic studies made by the Army Engineers, prior to the construction of the dam, limited the capacity of the reservoir to only 290,000 acre-ft at the spillway crest, which is equivalent to 4.5 in. of runoff from the tributary drainage area of 1,183 sq miles. Between the spillway crest and the top of the bulkhead sections an additional quantity of 88,000 acre-ft as surcharge storage is available. Fig. 4 shows the capacity of the reservoir in terms of elevation.

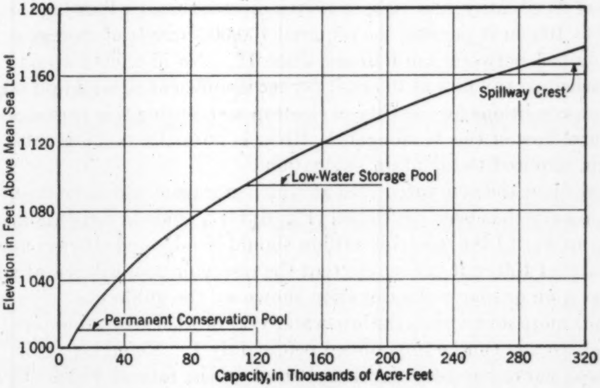

FIG. 4.—CURVE OF RESERVOIR CAPACITY

Seasonal Storage.—A schedule of dual-purpose operation is required for a flood-control reservoir of limited capacity if it must augment the seasonal low-water flow in the streams below the dam. The rate and quantity of low-water storage must be coordinated with flood-control operation to provide satisfactory results for both purposes. In allocating reservoir storage capacity to low-water regulation and flood control, during the months of low flow, a study was made to determine the water required to maintain satisfactory navigation conditions on the Monongahela River, under the most adverse conditions that might reasonably be expected. Using the historic 1930 drought as a criterion, it was determined that sometime it might be necessary to maintain a constant discharge of 340 cu ft per sec from the Tygart Reservoir for the 5½-month period from July 1 to December 15. Translated into volume, this flow would be 675 acre-ft per day, or 113,400 acre-ft for the 168-day period. The record of the Tygart River during the 1930 drought reveals that, although on occasion the discharge was as low as 1 cu ft per sec, the total volume of discharge from July 1 to December 15 was approximately 13,000 acre-ft. Since the difference between the total volume of required discharge and the minimum expected inflow determines the volume of storage that must be in the reservoir prior to the low-water period the use of 1930 as a criterion would necessitate 100,000 acre-ft of storage by July 1.

In planning the operation of the reservoir, it was necessary to determine when, and at what rate, storage should be impounded in order to have the required storage by this time. It is obviously desirable to reserve the entire reservoir capacity for flood storage during the periods when floods are most prevalent. A study of Fig. 5 shows the distribution by months of floods at Pittsburgh, and indicates that flood frequencies increase from November to March and decrease from April through October. Therefore, maximum storage capacity is maintained in the period from November to March and, since the probabilities of damaging floods begin to decrease in April, at this time a gradual increase in storage may be started. An analysis of stream discharge during the months of April, May, and June in 1930 indicates that, by limiting the reservoir outflow to 100 cu ft per sec, the required 100,000 acre-ft of storage could have been obtained between April 10 and June 15. No ill effects would be caused by this schedule as a flow of 100 cu ft per sec is sufficient to maintain satisfactory sanitation conditions for the City of Grafton and, during this period of the year, the natural flow of the Monongahela River is normally much greater than the minimum required to maintain navigation.

Based upon the computed rate at which storage could have been obtained in 1930, a curve has been developed (Fig. 6) for a guide in impounding storage. Starting on April 1 the reservoir outflow should be adjusted (always maintaining a minimum of 100 cu ft per sec) so that the reservoir pool will rise at a rate that will keep it on or above the elevation shown on the guide line. Thus, even if conditions more severe than the low-water year of 1930 are encountered, 100,000 acre-ft of storage can be impounded before July 1. Referring again to Fig. 6, a depletion curve has been developed showing the rate at which the reservoir pool would have receded in 1930, under a constant outflow of 340 cu ft per sec, assuming the total inflow for the period to have been equally distributed. If the rate of drawdown throughout the low-water season keeps the pool elevation on or above the guide-line requirement, it is reasonably certain that the guaranteed minimum discharge of 340 cu ft per sec can be supplied continuously from July 1 to December 15.

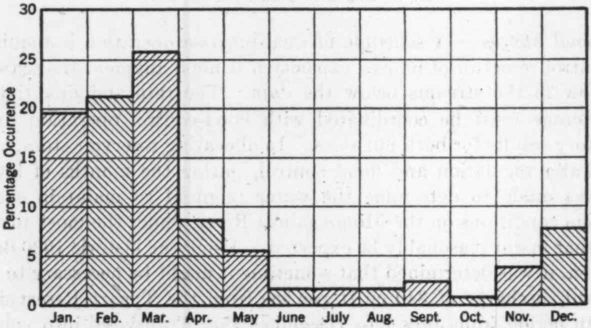

FIG. 5.—MONTHLY DISTRIBUTION OF PAST FLOODS AT PITTSBURGH, PA.

General Features of Flood-Control Operation.—As previously mentioned, the gross capacity of the Tygart Reservoir is equivalent to 4.5 in. of runoff from the tributary drainage area. However, when the low-water storage of 100,000 acre-ft is in the reservoir, the remaining flood-control capacity is equivalent to only 2.9 in. of runoff. Obviously a reservoir of this capacity cannot completely contain the entire runoff from a great storm of the type that occurs frequently over similar drainage basins in Eastern United States. This limited storage capacity, therefore, presents a problem of operation since the outlet works cannot be closed arbitrarily at the beginning of a flood and opened when the flood is past. A proper balance must be maintained between outflow and inflow so that the maximum benefits will be obtained from the available storage capacity. Flood storage in the reservoir should not begin until it will aid in preventing or reducing damage at some downstream point. As the flood passes and forecasts of stages indicate that an increased outflow from the reservoir will not arrive at the critical downstream points until after the rivers at those points have receded below damage stage, the rate of storage in the reservoir may be reduced by a gradual increase in reservoir outflow.

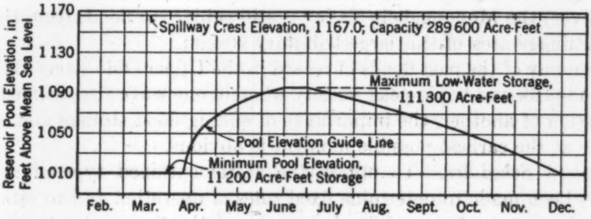

FIG. 6.—ANNUAL STORAGE SCHEDULE

The true functions of a reservoir of this type during a general flood are to delay the rise of its tributary flow only until the streams to which it is affluent are falling below damage stage, and to keep the magnitude of their ultimate rise below this critical point. This principle is shown diagrammatically in Fig. 7, which illustrates the necessity to store, not the entire flood flow, but only that part represented by the single cross-hatched area of the hydrograph. The double cross-hatched area represents the discharge of storage; the two areas,

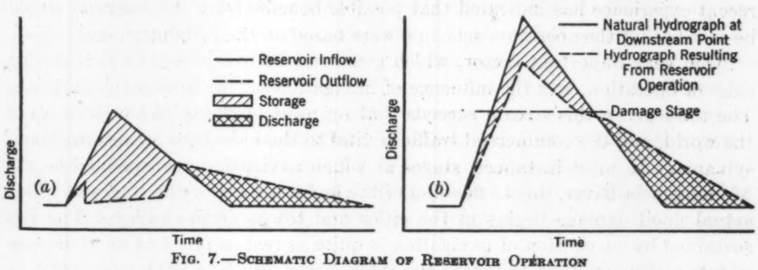

FIG. 7.—SCHEMATIC DIAGRAM OF RESERVOIR OPERATION

representing reservoir storage and draft, would, on an actual flood, be equal. The ideal result obtainable from this type of operation is shown diagrammatically in Fig. 7(*b*), which represents the desired effect at some distant downstream flood-damage point over which complete control cannot be procured. This condition obtains on the Monongahela River below Lock 7. Above this point the Tygart Reservoir can exercise almost continuous control over Monongahela River stages but beyond Lock 7 (which is immediately below the mouth of the Cheat River) the Monongahela Valley is still subject to floods from the uncontrolled drainage area of this large tributary stream.

Since many of the past floods of record in the Upper Ohio River Basin are of the double-peak and triple-peak variety wherein one wave rises immediately on the recession of another, the importance of ending flood storage and beginning discharge at the earliest possible moment is obvious.

Operation Schedules.—To obtain the aforementioned type of results, an effort has been made to determine fixed rules of operation and to establish criteria for the time and rate of flood storage and the time and rate of discharge of storage. The first attempt at establishing a fixed operation schedule was based upon stages at Pittsburgh, since it is in this district that the great monetary flood losses occur. From a study of past floods, a certain stage combined with a definite anticipated rate of rise on the Pittsburgh "Point" gage located at the confluence of the Monongahela and Allegheny rivers was set as the starting limit for storage in the Tygart Reservoir, and likewise a certain stage and rate of fall at Pittsburgh indicated the time for release of storage. Because of the complexities of the drainage basin above Pittsburgh it was soon evident that an operation schedule based entirely on stage conditions at this point would be subject to wide variation in results. The floods that occur at Pittsburgh are not always caused by simultaneous flood flows of the Allegheny and Monongahela rivers as either stream is sufficiently large, individually, to cause or contribute principally to flood stages in the Upper Ohio River. Therefore, although it is possible to set criteria at Pittsburgh that would have given excellent results from the Tygart Reservoir on some of the past great floods of record, recent experience has indicated that possible benefits from the reservoir would be sacrificed if the operation schedule were based on the Pittsburgh stage alone.

One very important factor, which could not be overlooked in establishing rules of operation, was the influence of navigation on the Monongahela River. The tonnage on this stream exceeds that on most of the inland waterways of the world, and the commercial traffic is vital to the industries of western Pennsylvania. In most instances, stages at which navigation is suspended on the Monongahela River, due to flooding of the locks, are below the stages at which actual flood damage begins in the cities and towns of the valley. The loss sustained by suspension of navigation is quite as real as physical flood damage in urban districts, and therefore the river stages affecting navigation must be taken into consideration in the regulation of the reservoir.

Because of its comparatively short dam section, Lock 5 at Brownsville, Pa., is usually the first lock on the Monongahela River to be inundated by a rising river and the last lock to return to normal service. This point, therefore, forms a control index for the entire river. If the Tygart Reservoir is operated to delay the inundation of this lock as long as possible or prevent it altogether, and if, during reservoir discharge, the outflow is regulated to keep the stage at Lock 5 below the top of the lock walls, then the maximum benefits should normally be obtained throughout the length of the Monongahela River Valley. In the current operation studies Lock 5 has been used to a large extent as the point on which operating criteria must be based, and in a later paragraph the results obtained at Lock 5 on several actual floods will be demonstrated. The experience gained thus far strongly indicates that predetermined rules will serve only as a partial guide for successful reservoir operation and maximum efficiency can only be accomplished from judicious use of accurate forecasted stages at the critical points. The following example will tend to illustrate this point.

The average flood-wave translation time from Tygart Dam to Lock 5 is approximately 14 hr. When the rivers are rising the Tygart Reservoir, to be most effective, must begin storage at least 14 hr before the predicted time for Lock 5 to be overtopped by an uncontrolled flood wave. Storage must continue at the maximum rate in the reservoir until it is predicted that 14 hr later the stage at Lock 5 will have receded below the top of the walls. The rate at which the reservoir outflow can be increased must be equal to, or somewhat less than, the predicted rate of recession at Lock 5. If all these conditions are forecast accurately the reservoir can be operated so that the loss of lock service will be reduced to a minimum, and the maximum reduction of the flood crest will also be obtained at Pittsburgh and other critical points throughout the length of the Monongahela River.

One possible objection to the use of Lock 5 for operation control is that positive storage in the reservoir may be used for the benefit of the Monongahela River when the river at Pittsburgh is below flood stage. If a great general flood should occur in the Tygart Basin immediately following this period, sufficient in magnitude to overtop the spillway of the dam, the efficiency of the reservoir might be reduced, as part of the storage capacity would be occupied at the beginning of the flood. This possibility can be greatly lessened by accurate meteorologic forecasts and intelligent use of hydrologic data.

Flood Prediction.—In the preceding section the importance of predicted river stages below a flood-control dam has been emphasized. It is evident, of course, that the forecast of inflow into the reservoir itself is of great importance, particularly where the storage capacity is limited and where there is a possibility that the reservoir will be completely filled by a large flood or succession of smaller floods. In this section some of the factors affecting flood prediction will be discussed briefly, and the sources of river and rainfall data will be enumerated.

The first factor to be considered in making river-stage forecasts is the condition of the streams at the beginning of the storm period. This is very important as a flood of some definite magnitude may be comparatively small if isolated. If it has occurred closely after another flood, however, which has utilized all the natural storage in the stream valleys, it may result in extremely harmful stages. The floods of January, 1937, in the Ohio Valley were of this type.

Another factor affecting flood flows is the percentage of runoff to be expected from a given rain. This is largely a function of the absorption capacity of the soil and condition of vegetation. A constant check on the rainfall-runoff relation must be maintained as it varies through the year. When they are unaffected by surface runoff, river stages represent outflow of ground water, or subsurface flow, giving an indication of soil conditions and the rate of infiltration to be expected with rainfall. Studies are being conducted along these lines to correlate these factors more accurately for use in determining runoff.

The most important factors in flood prediction, of course, are the rate and distribution of rainfall, combined when necessary with the water content of fallen snow. A network of rain gages and river-gaging stations is maintained over the Upper Ohio Drainage Basin by the U. S. Weather Bureau, U. S. Army Engineers, and U. S. Geological Survey. Daily reports from these stations are telegraphed to the Pittsburgh Office of the Weather Bureau at 7:00 a.m. and during periods of heavy rainfall at 6-hr intervals. The Weather Bureau, in conjunction with the Federal-State Forecasting Service, makes river-stage predictions for principal points in the Pittsburgh District of the U. S. Engineer Department.

In the tributary area of the Tygart Reservoir a network of ten rain gages and six river gages is maintained. From the reports of these stations, forecasts are made of reservoir inflow using runoff distribution percentages developed from a unit hydrograph for this basin. Fairly good results have been obtained and investigations are being made to define a small drainage basin above the dam to be used as an index of the runoff to be expected from the entire basin.

Accurate prediction of rainfall over an area before the rain has actually fallen represents the ultimate hope of those engaged in flood-protection work. Rapid strides in the science of air-mass analysis indicate that such predictions from data obtained by the Weather Bureau are a distinct possibility.

Flood Routing.—In simple terms, flood routing is an analytical redevelopment and transition of a flood wave—its inception from surface runoff in the headwater areas of one basin, its subsequent movement downstream augmented by inflow from successive tributary streams and diminished by the flattening of the wave as it progresses downstream, and the effect of natural valley storage. If the natural inflow from one of the tributary streams is withheld by a flood-control dam, the net effect at some downstream point will be a function of the valley storage between the dam and the point at which the reduction is computed. This amount of valley storage will itself be a function of the rate of discharge from the uncontrolled parts of the drainage basin.

The Army Engineers of the Pittsburgh District have been conducting extensive investigations into various analytical methods of flood routing and have adopted the so-called "coefficient method," first used in the Muskingum Watershed Conservancy Project studies, as the mathematical type most applicable to their region. In this method of routing, the stream is divided into routing reaches. The ends of these reaches are marked by stream-flow stations, so selected that the time of flow translation between the reach limits is as nearly equal as possible and corresponds somewhat to the interval of time used in routing computations. The flood wave is then routed analytically through each reach. The inflow at the head of the reach is added to the computed tributary inflow throughout the reach; and the inflows are modified for time, and by valley and wave slope storage. The outflow at the reach termination is thus determined.[4] The outflow so determined at the end of the reach is then checked against the actual flood hydrograph. A representative group of floods in the Upper Ohio Basin have been routed by this method and very close agreements between the reproduced flood hydrographs and the actual flood hydrographs have been obtained. The flood routing coefficients determined by this method of routing have been used in computing the reductions effected by the Tygart Reservoir at Lock 5 and at Pittsburgh.

Results from Flood-Control Operation

Floods Encountered.—It is a curious fact that, since the beginning of construction of the Tygart Dam, four floods have occurred that exceeded in crest magnitude all but one of the previous floods of a thirty-year period of record at this site. In descending order of peak discharge the first five floods of record on the Tygart River are those of July, 1912, October, 1937, April, 1939, February, 1939, and March, 1936. Since the dam was not fully completed until January, 1938, it was not possible to control all of the four recent large floods. Construction was not far enough advanced to have any appreciable effect on the flood of March, 1936; some control was exercised over the flood of October, 1937; and, during the floods of February and April, 1939, the dam was in full operation. One other flood occurred in December, 1937, which, although of minor proportions on the Tygart River, occurred coincidentally with flood stage at Pittsburgh.

October, 1937.—This flood was the second greatest of record on the Tygart River, reaching a peak reservoir inflow of about 52,000 cu ft per sec. The installation of the slide-gate machinery in the dam was not yet completed and one of the slide-gate conduits was closed by a bulkhead at this time. The upper reaches of the reservoir had not been completely cleared and the available storage capacity, therefore, was limited. During this flood the dam was operated as a detention reservoir. All seven available slide gates and both needle valves were open from the beginning of the rise until the reservoir was again empty. The inflow into the reservoir so far exceeded the capacity of the outlet works at a low storage head that some 104,000 acre-ft of storage were impounded in the reservoir. The rainfall causing this flood on the Tygart River was general over the entire Monongahela Basin with the result that navigation locks on the Monongahela River were flooded out and flood stage at Pittsburgh was exceeded. Fig. 8(*a*) shows the hydrographs of the Tygart Reservoir inflow and outflow, and Figs. 8(*b*) and 8(*c*) demonstrate the effect of the reservoir on the flood hydrographs at Lock 5 and at Pittsburgh.

---

[4] "Muskingum River, Ohio (308), Vol. IV," report of U. S. Engr. Office, Zanesville, Ohio, December 1, 1934.

December, 1937.—This flood was the first on which the Tygart Dam could actually be operated. The flood on the Tygart River itself was not particularly severe, the peak reservoir inflow being 22,000 cu ft per sec, but the flood stage at Pittsburgh was exceeded and the reservoir effected some reductions at this point. Fig. 9(*a*) shows the reservoir inflow and outflow, and Figs. 9(*b*) and 9(*c*) show the effect of the reservoir on the hydrographs at Lock 5 and at Pittsburgh.

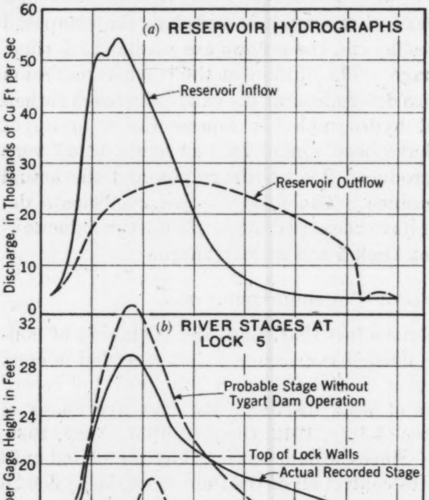

FIG. 8.—FLOOD OF OCTOBER, 1937

February, 1939.—This was a double-peak flood, the crests occurring on January 31 and February 4. The peak reservoir inflows were 28,000 cu ft per sec and 43,500 cu ft per sec, respectively, the latter being the fourth greatest of record in the Tygart River. Precipitation causing these floods was general over the Monongahela Basin and this river would have experienced a flood of major proportions had it not been for the Tygart Reservoir. Coming almost entirely from the Monongahela River and reaching flood stage at Pittsburgh, this flood furnished an example of the effectiveness of the Tygart Reservoir. The reservoir inflow and outflow are shown in Fig. 10(*a*), and the reductions of the flood hydrographs at Lock 5 and at Pittsburgh are shown in Figs. 10(*b*) and 10(*c*).

A double-peak flood of the type occurring on January 31 and February 4 furnishes a severe test of operation technique. Some of the storage impounded during the first peak was discharged as rapidly as possible when meteorological forecasts indicated the approach of additional rain. Referring to Fig. 10(*b*), it can be seen that the rate of discharge was so calculated that the Monongahela River was held stationary about 2 ft below the lock walls at Lock 5, thus allowing navigation to proceed on the entire river. Near the beginning of the second flood wave, storage was again begun in an effort to reduce this crest at downstream points. The total volume of reservoir inflow from January 30 to February 5, inclusive, was about 264,000 acre-ft. The maximum storage in the reservoir at any one time was only 128,700 acre-ft, so that it is evident that, by this system of operation, a possible third and greater peak could have been effectively reduced.

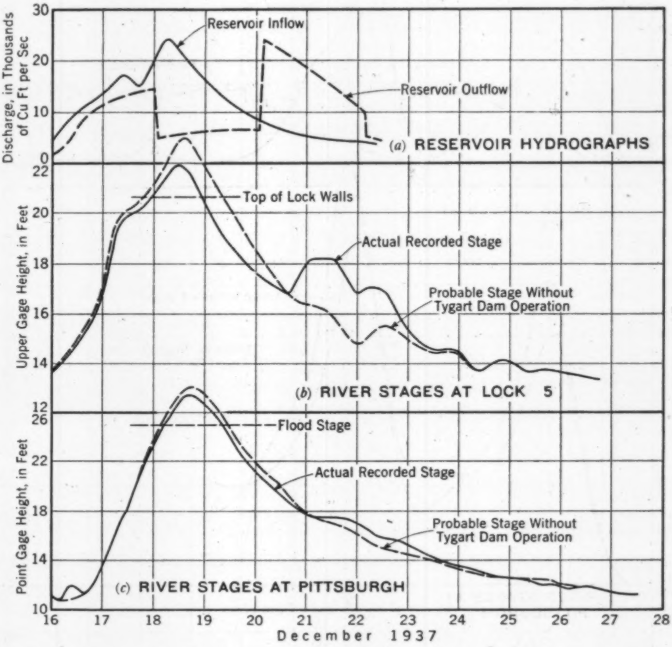

FIG. 9.—FLOOD OF DECEMBER, 1937

April, 1939.—At the beginning of April, 1939, storage was started in the reservoir for the purpose of impounding 100,000 acre-ft for use during the low-water season. The natural discharge of the Tygart River during the first two weeks of the month was such that about 90,000 acre-ft had already been impounded by April 14. With this volume of storage already in the reservoir another major flood occurred on the Tygart and Monongahela rivers. A peak reservoir inflow of 44,000 cu ft per sec on April 16 places this flood third in order of crest magnitude in the history of the Tygart River. A large flood of this type, occurring with the low-water storage already in the reservoir, furnished a thorough test of the capability of the Tygart project to perform its dual function of flood control and water supply. The results, as shown in Fig. 11, were satisfactory. During this flood the reservoir pool reached the

highest level yet attained at El. 1,144.75, representing a gross storage of 220,975 acre-ft. Although the net storage during the flood period was about 131,000 acre-ft there was still about 68,000 acre-ft of storage capacity available.

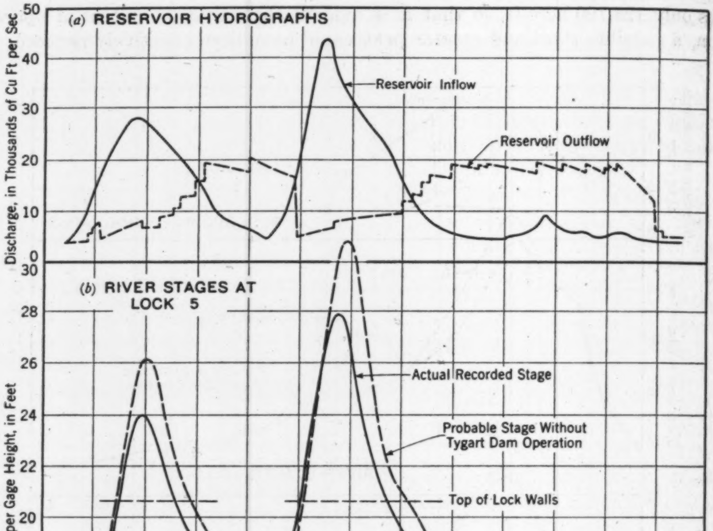

FIG. 10.—FLOOD OF JANUARY AND FEBRUARY, 1939

Minor Rises on Monongahela River.—There are frequent occasions throughout the year when a sharp rise in the rivers will threaten the suspension of Monongahela River navigation without approaching actual flood damage stages. On these occasions the Tygart Reservoir is utilized to equalize, as far

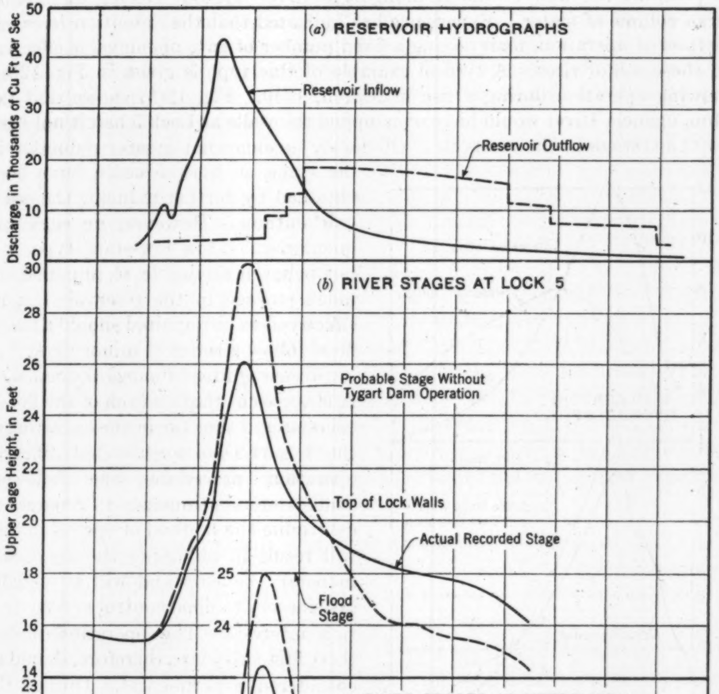

Fig. 11.—Flood of April, 1939

as possible, the flow of the Monongahela River without storing an unduly large volume of water. Experience has indicated that the detention reservoir method of operation, maintaining a fixed number of gate openings, is effective on these minor rises. A typical example of this type is given in Fig. 12(*a*), showing operation during a rise in March, 1940. Fig. 12(*b*) shows that the Monongahela River would have overtopped the walls at Lock 5 had it not been for the storage in the reservoir. Obviously, a somewhat greater reduction in the stage at Lock 5 could have been obtained by further reducing the reservoir outflow. However, on such frequent rises of this low-stage type, it is not believed advisable to impound too much storage in the reservoir lest its effectiveness be impaired should a major flood follow a series of minor rises.

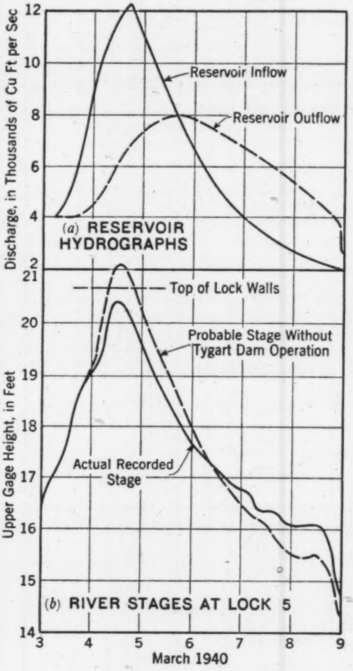

FIG. 12.—FLOOD OF MARCH, 1940

Review of Flood-Control Operation.—It is apparent that on each of the floods encountered thus far in the operation of the Tygart Dam a somewhat different operation procedure was followed. Studies are continuously in progress to determine the method of operation that will result in obtaining the maximum monetary benefits and will be equally satisfactory to flood control and navigation interests. The operation during these first two years, therefore, should be considered experimental. During the flood of December, 1937, an effort was made to correlate the time of reservoir storage with the river stage at Pittsburgh. As a consequence, the maximum possible rate of storage was delayed until nearly the time of the peak reservoir inflow. The rate of discharge, also based on the Pittsburgh gage, produced somewhat undesirable conditions on the Monongahela River. In the flood of January–February, 1939, it was found that an attempt to maintain a fixed passing flow during the storage period, and an increasing discharge rate after the flood had passed, resulted in excessive manipulation of the gates and valves and an extremely irregular hydrograph immediately below the dam. This flood also emphasized the fact that, to be most effective, storage must be started in the reservoir at the beginning of the rise in inflow without waiting for a predetermined stage at some downstream point.

Somewhat better results might have been obtained had storage been started about six hours earlier on the second peak. During the flood of April, 1939, the operation was predicated largely upon forecasted stages at Lock 5. The passing flow during the storage period was maintained at the capacity of one slide gate, thus increasing the outflow as the available storage capacity was decreased. The rate of discharge after the flood peak had passed permitted the Monongahela River to maintain a steady recession at the navigation locks and was satisfactory to navigation interests. The operation during this April flood is believed to be the most successful yet attained and will be used as a guide on future floods of a similar nature.

Monetary Benefits from Flood Control.—In planning the system of flood-control reservoirs a very comprehensive study was made of flood damages in the Upper Ohio River Basin to determine the benefits that would result from reductions of flood peaks. The details of this damage study are quite extensive and only the results are presented herein. The Monongahela Valley has been divided into three damage districts as follows: Pittsburgh District, from the junction of the Ohio and Beaver rivers to Lock 2, Monongahela River; McKeesport District extending from Lock 2, Monongahela River to Lock 4, Monongahela River; Upper Monongahela District from Lock 4 to the head of the river. Damage curves for these three reaches of the river, as developed from the comprehensive study of flood damages, are shown in Fig. 13. The reductions of the crests effected by the Tygart Reservoir on the floods shown in Figs. 8 to 12 were applied to the damage curves to determine the flood-control benefits attributable to the Tygart project. The results in detail are presented in Table 1, the total sum being $2,818,000.

LOW-WATER REGULATION; NAVIGATION

One of the primary purposes of the construction of the Tygart Dam was to provide a storage reservoir to supply an adequate flow for navigation during the low-water season. Prior to the construction of the Tygart Dam, there were many occasions when the natural flow in the Monongahela River was not sufficient to maintain full pools behind the navigation dams. When the volume of water required for lockages, plus the normal leakage past the dams, exceeded the natural flow of the river, the pools would recede below the dam crests and the navigable depths in the pools would be reduced, thus necessitating lighter loading of barges and an increased number of towboat trips to haul the same tonnage. The historic example is the drought of 1930 at which

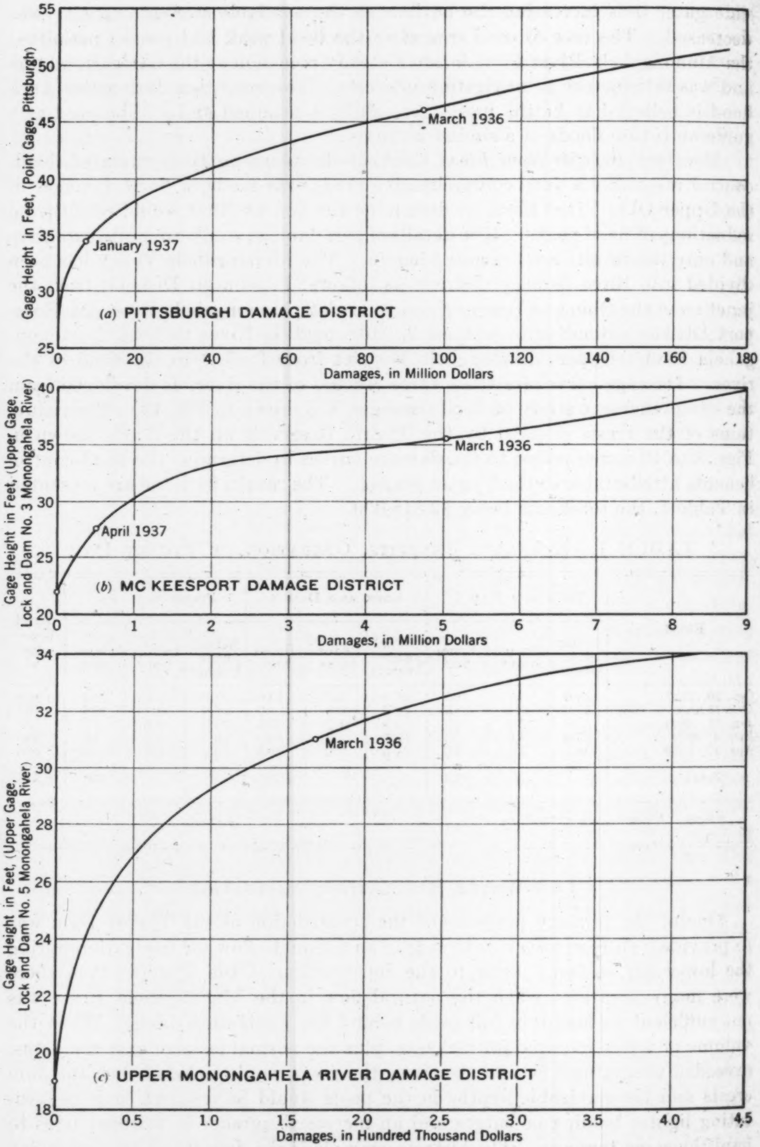

FIG. 13.—APPROXIMATE FLOOD DAMAGE (1936 DOLLAR STANDARD)

time navigation was completely suspended above the pool of Lock and Dam 7, and was maintained at a restricted rate below Lock 7 only by virtue of water obtained from a hydroelectric development on the Cheat River. The action of the Tygart Reservoir in alleviating this condition during the two years 1939 and 1940 has been effectively demonstrated, especially during the late summer and early fall of 1939 when the most severe low-water conditions since 1930 were encountered. Fig. 14 shows the daily reservoir pool elevations for 1938 and 1939, demonstrating the time and rate of storage and discharge.

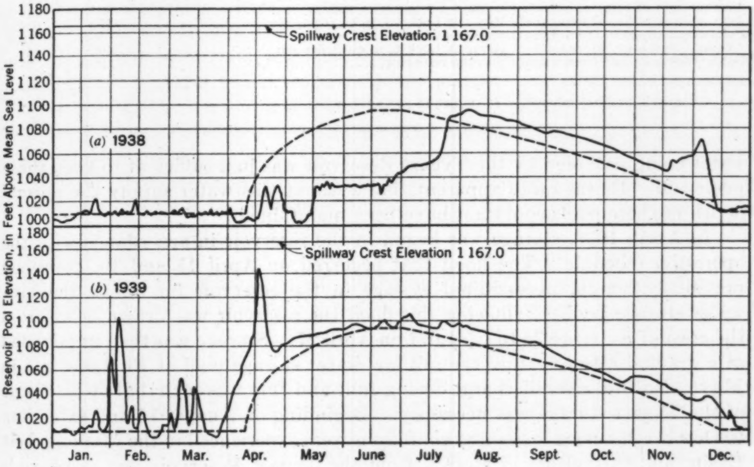

FIG. 14.—DAILY POOL ELEVATIONS

In 1938 it was not possible to begin storage in the reservoir in April (as called for on the operation schedule) because of complications in land acquisition in the reservoir area. Storage was finally begun late in June, and by July 20 about 40,000 acre-ft had been impounded by limiting the outflow to 100 cu ft per sec. Fortunately the natural flow of the Monongahela River was sufficient to permit this procedure. On July 20 and 21 a storm occurred over the Tygart Basin and, by storing almost the entire runoff, the full storage pool of 100,000 acre-ft was obtained by August 1.

Release of this storage was begun on August 6 when the Monongahela River began to recede to low stages, and proceeded continually to November 18. The data in Table 2, Col. 2, demonstrate the increase in the low-water flow provided by the reservoir storage during this period.

The low-water season of 1938 was not particularly severe except for about two weeks in late August and early September. However, the effect of the release of storage from the Tygart Reservoir produced conditions so far superior to those experienced in normal years that this feature of the reservoir operation resulted in widespread public approval. A head of 0.5 ft was maintained on the crests of the navigation dams on the Monongahela River from Dam 15 to Dam 7, inclusive, throughout the low-water period. Below Dam 7 the head on the dam crests was less than 0.5 ft due in part to the greater number of lockages in the lower reaches of the river. In late August and early September the pools behind Dams 5 and 6 receded to the dam crests and the additional water being provided by the Tygart Reservoir was just sufficient to keep these pools full. It was quite apparent that without this water supply the normal depth in these pools could not have been maintained.

TABLE 2.—LOW-WATER REGULATION

Description (1)	1938[a] (2)	1939[b] (3)
Total volume of storage released, in acre-ft	69,800	60,950
Average rate of release, in cu ft per sec	334	433
Average discharge, Monongahela River at Lock 15, in cu ft per sec	570	624
Percentage supplied from Tygart storage reservoir	58.7	69.5
Average discharge, Monongahela River at Lock 5, in cu ft per sec	1,404	1,135
Percentage supplied from Tygart Storage reservoir	23.8	38.2

[a] August 6 to November 18. [b] August 15 to October 25.

In April, 1939, storage was begun in the reservoir in accordance with the operation schedule. The flood that occurred on April 15 and 16, described previously herein, necessitated storage in the reservoir far above the low-water storage pool. Following this flood the reservoir was drawn down from the crest of El. 1,144.75 to El. 1,077 on April 27. Storage was then impounded at a gradual rate to attain the full low-water storage pool at El. 1,094 late in May. Natural river discharge during June and July was such that no discharge of the Tygart storage was necessary. Beginning on August 15 and extending to October 25 severe low-water conditions were experienced in the Monongahela Basin, and the release of storage from the Tygart Reservoir was responsible for maintaining unrestricted navigation on the Monongahela River. The data in Table 2, Col. 3, illustrate the effectiveness of the reservoir on the Monongahela River discharge.

As a result of this regulation by the Tygart Reservoir, conditions on the Monongahela River were maintained much the same as during the previous year. A 0.5-ft head was held on the dams from Lock 15 to Lock 7, whereas the pools at Locks 6 and 5 were barely full. The marked deficiency of rainfall and the acute low-water conditions on other streams of the Pittsburgh District made the effect of the Tygart storage on the Monongahela River quite apparent to the general public and many favorable comments were expressed by those interested in river transportation.

Evaluation of the monetary benefits attributable to the Tygart Reservoir during this period were made through recourse to the records of the 1930 drought. In that year the low water began about July 1 and by July 20 the pool at Lock 5 had receded 4 ft below the crest of the dam, and navigation was seriously impaired. Several slight rises in discharge increased the pool depth about 2 ft, but in mid-September a deficiency of slightly more than 4 ft existed and navigation authorities declared that, should conditions become any worse, it would be impossible to navigate towboats on the Monongahela River. Subsequently, arrangements were made to obtain the storage impounded in the hydroelectric development on the Cheat River for low-water control. This additional flow was just sufficient to maintain navigation in the lower part of the Monongahela River, but in the upper reaches of the Monongahela River, above Lock 7, the pools with the exception of Lock 10 were completely empty and navigation had ceased entirely.

A comparison of the stream-flow records of 1930 and 1939 reveals, of course, that the 1930 drought was more prolonged and severe than that of 1939. However, the conditions experienced from mid-August until late October in 1939 are comparable with the early period of the 1930 drought.

Since the increase in flow (amounting to a total of 60,950 acre-ft) provided by the Tygart Reservoir was barely sufficient to keep the low Monongahela navigation pools full, it is certainly evident that under natural conditions these pools would have been well below the dam crests.

In 1930 information was obtained from the larger companies engaged in Monongahela River traffic to the effect that complete suspension of navigation would result in increased direct costs to these companies of about $1,230,000 per month. It was also estimated at that time that restricted navigation with the pools below the dam crests resulted in increased costs of approximately $139,000 per month. The average monthly Monongahela River tonnage for July, August, and September of 1930 was 2,130,930 tons. In August, September, and October of 1939 the average monthly tonnage was 2,160,900 tons.

The navigation pools of the river would have unquestionably fallen below the critical dam crests for at least two months in 1939 and, since the volume of traffic was comparable to that of 1930, a direct saving of at least $140,000 per month, or $280,000 for this low-water period, was effected. A determination of the exact amount which the navigation pools would have receded under natural conditions was considered inadvisable, as the quantity of water lost by leakage can only be approximated. It is problematical, therefore, whether or not navigation could have been maintained even constantly in a restricted manner throughout the dry period without additional water supply. The cost figures obtained in 1930 pertain only to the additional cost of providing coal by means other than river shipment to the industries normally served by water transportation. The far-reaching indirect effects of disrupted transportation and delayed shipments upon the plants immediately concerned and the general effect upon other related industries cannot be readily reduced to a money basis. Therefore, the estimated saving of $280,000, representing only direct additional costs of coal shipments and based on the assumption that navigation could have continued in a restricted manner without the Tygart Reservoir, is believed to be extremely conservative.

LOW-WATER REGULATION; WATER SUPPLY AND SANITATION

General.—The seasonal storage in the Tygart Reservoir and the regulation during the low-water periods is based primarily on the demands of Monongahela River navigation. However, since this river is extensively used as a source of domestic and industrial water supply and at the same time as a disposal channel for sanitary and industrial wastes, any increase in the seasonal low-water flow constitutes a major benefit to industry and to the general public in the Monongahela Valley. Deplorable conditions existed in the Monongahela River during the 1930 drought, constituting a serious menace to the public health. The improved condition of the river water since the Tygart Dam has been placed in operation has been quite apparent at the water works and industrial plants on the river.

Quality of Tygart River Water.—In the drainage area tributary to the Tygart Reservoir there is a sewered population of from 15,000 to 20,000 persons discharging domestic wastes directly into the river. Industrial development above the dam is sparse, there being but two plants of any size using the river for industrial disposal. During periods of low-water flow the West Virginia State Department of Health has recognized major sewage nuisance conditions in the vicinities of Philippi, Buckhannon, Belington, and Elkins and sewage treatment plants are contemplated for the latter two towns. There has been rather extensive coal-mining activity in the area above the reservoir, and the drainage from abandoned mines imposed an acid load upon the streams. Activities of the federal government in the mine-sealing field have resulted in the sealing of 124 out of 187 abandoned mines above the Tygart Reservoir.

The storage period of the Tygart Dam begins early in April (see Fig. 6). Ordinarily the major part of the 100,000 acre-ft of storage will be impounded during the spring freshets of April and May. During these periods of high river stages the water is turbid but relatively pure, and this vast supply in the reservoir serves as an effective dilution basin for the contaminated low-water flow in the dry summer months. The City of Grafton, immediately below the dam, obtains its raw water supply directly from the reservoir and considers this source far superior to the run-of-river supply previously used. The West Virginia Department of Health has classified the water in the reservoir as "safe."

[a] At the dam. [b] In cubic feet per second. [c] At Charleroi, Pa. [d] Beginning August 6, 1938. [e] Total. [f] Beginning June 7, 1939. [g] Average, both periods.

Chemical analyses of the water discharged from the reservoir during the past summers have been made and the average values are as follows: Alkalinity, 5 ppm; soap hardness, 29 ppm; turbidity, 7 ppm; free carbon dioxide (CO_2), 3 ppm; potential of hydrogen (pH), 6.1; temperature, 68° F; and indicated number of B. coli (24 hr presumptive), 1 per 10 million. Turbulent discharge through the needle valves insures a dam-site flow that is high in dissolved oxygen, thus aiding in the assimilation and purification of domestic and other wastes that have a high oxygen demand.

Increase in Flow of Monongahela River.—Disposal by dilution is an accepted method of handling almost all of the common wastes incident to human and industrial activities. The success of the method is dependent upon the quantity and quality of diluting water available. The quality of the Tygart Reservoir water has been discussed, and Table 3 gives the increase in low-water flow supplied to the river during various critical periods of 1938 and 1939. Under the heading: "Low-Water Regulation; Navigation," average values were given for the increase in the low-water flow for a continuous period in 1938 and 1939. The values contained in Table 3 are for intermittent critical periods and are based at different points.

Chemical Changes in Monongahela River.—An estimate has been made of the probable effect of the Tygart Reservoir on the chemical characteristics of the Monongahela River during the low-water seasons of 1938 and 1939. Chemical analyses of the reservoir water and of the river as recorded by the various water works and industrial plants along its course were obtained continuously throughout these periods. The approximate natural discharge of the river, as it would have been without the additional discharge from Tygart Reservoir, was determined. Stream-flow records were investigated to find years prior to the construction of Tygart Dam when the Monongahela River discharge compared closely with the natural discharge during 1938 and 1939.

From the past records of water works and industrial plants the chemical characteristics of the water during these years of similar flow were obtained. After a thorough study of all the factors involved a computation was made of the chemical effect of the Tygart Reservoir water and the results are shown in Table 4.

Monetary Benefits.—The total quantity of water consumed for various purposes throughout the length of the Monongahela River was determined by a field investigation of the records of the municipal water works and industrial plants. These data are shown in Table 5*A*. At the same time time the method and cost of water treatment were ascertained to be as follows:

TABLE 5*A*.—WATER CONSUMPTION, MONONGAHELA RIVER, IN MGD

TABLE 5*B*.—MONETARY BENEFITS (ADD 000)

1938 and 1939	....	....	....	....	2.7	102.9	75.7	99.8	281.1

Neutralization (lime at $12.00 per ton), in cents per million gal, per ppm of acidity neutralized..........................	5
Softening (lime at $12.00 per ton and soda ash at $1.25 per 100 lb), in cents per million gal, per ppm of hardness removed......	25

A combined adjustment of water consumption with the reduction in acidity and hardness effected by the Tygart Reservoir and the unit costs of water treatment (in thousands of dollars) produce total monetary benefits as shown in Table 5*B*.

Review of Water-Supply Benefits.—The monetary benefits in Table 5*B* include only the estimated savings in actual water treatment. No attempt has been made to assign monetary values to various factors, such as the increased oxygen-carrying capacity that aids in the assimilation of domestic sewage and other organic and inorganic wastes. The possible effect on the Ohio River below Pittsburgh has also been omitted. The estimates of monetary benefits, therefore, are believed to be conservative.

Although the operation of the Tygart Dam for low-water supply is only one step forward in the desired purification of the rivers of the Upper Ohio Basin, the presence of this reservoir does insure the population of the Monongahela Valley against repetition of the conditions of 1930. This feature of the project is an important by-product of the primary functions of navigation and flood control.

CONCLUSION

The total monetary benefits attributable to the Tygart Dam for the first two years of operation are as follows: Flood control, $2,818,000; navigation, $280,000; and water supply, $281,100—a total of $3,379,100. Monetary benefits have been determined only where direct savings to the public can be shown. The direct benefit for the maintenance of navigation is most misleading because, as explained previously, many intangible factors, including delay and disruption of industrial production, are too complicated to be evaluated fully in a paper of this nature. The effect of the Tygart Reservoir in maintaining unrestricted navigation on the Monongahela River throughout the summer and fall of 1939 is probably the greatest single benefit attributable to this project.

The moderate reductions effected on flood crests at Pittsburgh by this one reservoir, controlling only about 6% of the total drainage area of the combined Allegheny and Monongahela rivers, serve as an indication of results that may be obtained from the proposed ten-reservoir system. It is also worthy of mention that, although the net reduction in the flood peak is the most important factor in evaluating flood damages, there is also the factor of time that the river remains above damage stage. On some of the floods discussed herein the degree of synchronization of the peak discharges of the Tygart River with those at Pittsburgh was such that only a small reduction in crest stage was effected, but it was accompanied by a much greater reduction during the recession of the flood, with a corresponding reduction in the time that the river remained above flood stage. This time element is particularly important at the locks of the Monongahela River, and the reduction in the time that these locks would have been out of service is one of the important intangible benefits to which no monetary values have been ascribed.

These first two years of operation most probably do not represent average annual conditions since three of the five largest floods of record on the Tygart Basin occurred during this time and the Monongahela Basin experienced one of the worst droughts in its history. On the other hand, only small floods with low damages have occurred at Pittsburgh during this period. A small reduction on a larger flood would result in greater flood-control benefits than have thus far been obtained on any individual flood.

In conclusion, it is believed that the results achieved thus far by the Tygart Dam, even in the experimental stage, amply justify the funds expended for its construction and operation and are the most conclusive proof that can be offered for the extension of the flood-control system of the Upper Ohio River Basin.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Lieut.-Col. W. E. R. Covell, M. Am. Soc. C. E., U. S. Army retired, who supervised the preparation of this paper during his tour of duty as district engineer for the Pittsburgh Engineer District. Acknowledgment is also made of valuable contributions by E. P. Schuleen, Assoc. M. Am. Soc. C. E., V. L. Bohden, and E. W. Landenberger, all of the U. S. Engineer Office.

DISCUSSION

NICHOLLS W. BOWDEN,[5] M. AM. SOC. C. E.—The engineering profession in general, and hydraulic engineers in particular, who are interested or engaged in the operation of large reservoirs, or problems connected with them, should feel indebted to the authors for their clear, detailed, and comprehensive treatment of the Tygart Reservoir. There is a dearth of such material both in technical journals and in textbooks. Because of his connection with this and the other proposed storage projects above Pittsburgh while employed by the Corps of Engineers during several years of investigation and planning of these projects and until the construction of the Tygart Dam was well under way, the writer was greatly interested in this timely paper.

The dire need for this reservoir cannot be questioned when one considers the situations brought about by the severe drought in 1930 and the destructive flood in 1936. At times during the drought the natural flow in the Monongahela River was so small as to be negligible—far from enough to provide for lockage of boats and leakage through the locks and dams—and some of the pools in that river above the mouth of the Cheat River became practically empty basins. Below the confluence of the Cheat River, where the bulk of the commerce on this heavy-traffic waterway moves, water released from a privately owned power reservoir on the Cheat River was sufficient in the emergency to supply the pools and maintain navigation. The ravages of the 1936 flood, particularly in the "Golden Triangle" of the City of Pittsburgh, are too well known to need comment here.

As to the efficacy of the Tygart Reservoir in regulating flood flows and affording an adequate, dependable flow during the season of low natural discharge, the authors show quite conclusively that operations during the first two years have been successful. Very properly they state that: The reservoir controls only about 6% of the total drainage area of the Allegheny and Monongahela rivers above Pittsburgh; that the flood storage capacity equals only 4.5 in. of runoff over the contributing area above the dam; and that this capacity is insufficient to store the entire runoff from great storms such as frequently occur in the eastern part of the United States. The relatively small part of the runoff from the drainage area above Pittsburgh that this reservoir regulates is a potent argument for constructing additional reservoirs—and this is now being done—to regulate runoff from a larger part of the area. The relatively small flood-storage capacity of the reservoir seems to merit further discussion, as it is believed that this feature is of the utmost importance in the successful operation of this and other reservoirs. Also, the writer believes that there may be some who do not think that the degree of control which this reservoir affords is adequate.

Various criteria have been advanced for planning and designing reservoirs for flood control in this section of the United States. Some of these may be stated as follows: (1) That the flood-storage capacity should be equivalent to 8 in. or more of runoff over the controlled area; (2) that the flood-storage capacity plus a constant release from the reservoir at bankfull stage downstream, over a given flood period of, say, three or four days, should equal 8 in. or more of runoff; or (3) that the flood-storage capacity should be equivalent to at least one half the average annual runoff. All of these are desirable requirements, if attainable. The capacity of Sacandaga Reservoir in the Hudson River Basin is equivalent to almost 14 in. of runoff; that of the flood-storage space in Norris Reservoir in the Tennessee River Basin, about 12.5 in.; and that of the flood storage space in Lake Mead in the Colorado River Basin, more than three fourths of the average annual runoff. These multiple-purpose reservoirs easily meet the foregoing specifications for flood storage, as no doubt other reservoirs do, and there should be no question as to their suitability for flood control.

---

[5] Prin. Hydr. Engr., and Head, River Control Section, TVA (Formerly Senior Engr., and Chf., Projects Div., U. S. Engr. Office, Pittsburgh, Pa.).

Some years ago a prominent engineer remarked to the writer, in a facetious manner, that the planning of large reservoir projects in the Ohio River Basin came about 100 years too late; otherwise, a dam might have been built at or near the mouth of each tributary stream of sufficient height to control flood flows from above and then one on the lower reaches of the Ohio River itself, behind which all of the flood flow from the main-stream drainage could be controlled. This was just a trite way of saying that human occupancy of the valleys with cities, towns, industries, and rail and highway transportation lines had progressed so far that very large reservoirs were no longer feasible. He might have added with equal force that this human occupancy, which had much too often invaded the flood plain, made flood control increasingly important.

Thus, the situation in the Pittsburgh District that confronted engineers who planned the reservoir systems on the Allegheny and Monongahela rivers was one of very great need for flood regulation, as well as for other purposes, and usually of very definite limitations in storage possibilities except at high cost. If the engineers had adhered rigidly to conservative requirements for runoff-storage relationships, a reservoir plan suitable for the protection of the Pittsburgh area might not have been developed. Instead, the studies proceeded on the basis of securing as high a degree of runoff control as possible, giving due regard to the ratio of estimated annual costs to estimated annual benefits.

In order that the writer may not be misunderstood, it should be stated that he is a firm believer in providing ample storage space in reservoirs for complete control of flood runoff wherever feasible, but he does not believe that this important factor should be allowed to control to the exclusion of all other considerations. As the technique for operating large reservoirs improves—and it is improving rapidly—many concepts of yesterday and even of today will undergo marked change. The importance of collecting adequate precipitation data, and translating them quickly and accurately into stream flow, is now recognized as never before; the technique of routing flood flows in open channels and through reservoirs has advanced to a marked degree in recent years; and last, though probably far from least in possibilities of influencing and perhaps revolutionizing the method of operating reservoirs, is the effort being made by the U. S. Weather Bureau to forecast the location, amount, and intensity of rainfall one or more days in advance. Their initial cooperation in work of this character with the Tennessee Valley Authority in the Tennessee Basin, which was begun in 1939, is being followed closely to see what degree of dependability and accuracy can be attained.

Since the space available in the Tygart Reservoir for storing flood water is insufficient for complete control of the contributory area, it is essential to operate the reservoir in such a manner that the space is used when it will be most effective in accomplishing as much flood-stage reduction as practicable at the critical point downstream, and so that the space again will be made available in the reservoir as promptly as possible for subsequent use. The authors show that this principle has been applied with success in the regulation of floods thus far. Obviously, such operations require very careful attention and the exercise of good judgment in the use of the storage space, lest a storm should exceed expectations and produce a volume of runoff beyond estimates either in the form of a higher or broader inflow hydrograph, or possibly one with a double peak like the flood of January and February, 1939. A full reservoir at the wrong time might conceivably result in a high discharge rate from the reservoir at such time as to synchronize with peak flows at one or more critical points downstream. Involved in this problem is the matter of determining whether to attempt the maximum stage reduction, through the use of all available flood storage space to regulate a current flood, or whether to be satisfied with a smaller stage reduction and thus retain storage space as a factor of safety for use in case subsequent flood flows should develop.

The existence of operating problems of this nature, although difficult of solution, should not of itself deter engineers from constructing large multiple-use reservoirs that do not afford as much storage space for the several purposes as might be desired. The importance of the need and the value of such a project to society should have great influence. The writer has complete confidence in the ability of engineers to develop operating techniques, where necessary (such as the authors indicate is being done in the case of the Tygart Reservoir), which will depend for success on the proper handling of water rather than on storing all flood runoff in a catchment basin so large as to be almost foolproof in operation. Likewise, he believes that engineers are resourceful enough to perfect means for the efficient operation of large multiple-purpose reservoir systems.

EDGAR E. FOSTER,[6] **ASSOC. M. AM. SOC. C. E.**—The authors are to be commended for presenting a study of the results of the operation of one of the recently constructed multiple-purpose flood-control projects that the federal government has undertaken in the past decade. Few such projects have been completed long enough to observe the results of operation for a significant period of time. In the pioneer flood-control works constructed by the Miami (Miami Valley, Ohio) Conservancy District,[7] each dam was a single-purpose project only, since it used uncontrolled outlets for emptying the reservoir, and hence its operation could not constitute a complete model for the multiple-purpose projects.

[7] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1503.

The purpose of the Tygart Reservoir as stated by the authors is twofold—flood control and water conservation. The latter purpose provides water obtained from floods or high discharge in spring for the improvement of navigation, incidental benefits to water supply, and reduction of pollution during late summer. The utilization of the conservation water requires only releasing during periods of low stages at the controlling points along the stream below. The operation for flood control, on the other hand, must be planned carefully to obtain the desired result or even to prevent a worse flood. The seasonal basis for operating the Tygart Reservoir is depicted in Fig. 5. The plan of operation for both flood control and utilization of the conservation water has been skilfully developed.

Table 6 summarizes the reduction in flood peaks obtained at the site, at Lock and Dam 5, and at Pittsburgh, Pa., by operation of Tygart Reservoir. Generally, the reductions obtained at Tygart are much greater than at either Lock 5 or Pittsburgh, especially in the larger floods. Flood crests from storms centering over the headwaters of the Monongahela River, of course, will be reduced more effectively than storms centering elsewhere on the watershed. Although the reductions at Pittsburgh appear relatively small, they do not seem out of proportion to the drainage area controlled by the Tygart Reservoir as compared with the area above Pittsburgh.

TABLE 6.—SUMMARY OF FLOOD PEAK REDUCTIONS

Date	REDUCTIONS, IN FEET, AT:		
	Tygart	Lock 5	Pittsburgh
Oct., 1937	28.0	3.8	1.6
Dec., 1937	0.1 ±	1.1	0.5
Jan., 1939	8.0	2.2	0.8
Feb., 1939	24.0	3.0	0.6
April, 1939	26.0	3.8	1.8
March, 1940	4.2	0.6	....

Although the general principles of operating a flood-control reservoir are applicable to any watershed, the details of the operating plan must usually depend upon the characteristic features and requirements of each individual basin. Among the peculiarities to be considered in relation to the Tygart Reservoir are its location in the headwaters, the areas susceptible to flood damage at Pittsburgh and in the Monongahela Valley, the existing navigation on the river, the low spillway capacity, and the central location of Dam 5. The stage at Dam 5 is utilized as a control for the release of flood storage. These factors are used in developing the plan of operation of Tygart Reservoir but of course would not be available on any other watershed. On other streams and for other reservoirs a different set of characteristics necessarily would be considered.

Usually the large industrial centers like Pittsburgh that are subject to heavy flood loss would be the controlling point for reservoir operation, but the authors have shown that navigation is of such importance on the Monongahela River that a control point near the center of the basin must be selected. It appears to the writer, however, that Pittsburgh should be considered as a secondary control point for operations in the event of a general flood covering the Allegheny Basin.

A storage reservoir can reduce downstream flood crests by two means: (1) Storage until the flood has subsided throughout the basin, or (2) by delaying the peak at the site until the flood crest of the valley below has moved downstream. The latter plan is uniquely available to a reservoir in the headwaters. It has been used effectively in the operation of Tygart Reservoir as may be seen in the hydrograph of the flood of December, 1937; practically no reduction of peak was obtained at the site, where it was merely delayed, but a reduction of 1.1 ft was achieved at Lock 5. The floods of 1939 likewise show the effect of regulation to delay the peak as well as to reduce it by temporary storage.

The reduction of peaks on the main stem, by a delaying operation at the reservoir, is dependent to a considerable extent upon the location of the reservoir with respect to the main stem. Tygart Reservoir, being situated in the headwaters of the main stem, is favorably located for such operation. In order to illustrate a contrary condition, assume that floods on the Youghiogheny River under natural conditions discharge into the Monongahela River slightly ahead of the crest on the main stem. Under this condition a small reservoir located near the mouth of the Youghiogheny River, unable to hold a substantial part of the flood runoff, would succeed only in delaying the tributary crest, cause it to coincide more closely with the peak on the main stem, and thereby produce a greater flood below the mouth of the tributary. The location of a reservoir near the mouth of the Youghiogheny River and the relative time of the tributary flood is suppositive as far as the writer is aware, but it serves to illustrate the fact that merely delaying a flood crest on a tributary is not always advantageous, although it operates favorably for flood control by Tygart Reservoir.

A flood on a river is not a simple summation of excessive areal runoff as some theoretical studies may lead one to believe, but it is a compound product of the various peaks of its tributaries that combine at different times and places. The "flood-wave" analogy should not be taken too literally.

As another aspect of reservoir operation, the authors emphasize the element of flood prediction both above and below the reservoir. This emphasis is rightly placed, for some measure of discharge prediction at the reservoir and stage prediction at the control point is essential for efficient operation. Such flood prediction should be obtained with the closest possible cooperation with the Weather Bureau and the Water Resources Branch of the U. S. Geological Survey, such as the authors indicate is accomplished. The writer believes that snow surveys should also be utilized to secure data of the moisture content of snow cover if there is any possibility that such cover can contribute an appreciable proportion of the flood runoff.

THE SURVEYOR AND THE LAW

By A. H. Holt,[1] M. Am. Soc. C. E.

With Discussion by Messrs. E. F. Chandler, Harry Rubey, William H. Richards, Jr., C. B. Humphrey, and D. D. Haines.

Synopsis

It is not intended that this paper shall discuss, primarily, the law of boundaries. That is a very broad subject, capably treated in at least three books which, in whole or in part, are directly concerned with the subject.[2] The subject is also included, as incidental material to even broader subjects, in many treatises and compilations to which one commonly turns in efforts to learn the law. It is desired to present herein a discussion of those aspects of law which tend to indicate and to define the duties and the responsibilities of surveyors in their share of the work of establishing, describing, and recovering the boundaries of land. This is work in which there must be combined (with mutual understanding if best results are to be secured) the training, the experience, and the well-counseled efforts of practitioners of law and of engineering. This paper is a humble attempt to contribute a little to this end by discussion of some impacts of the law on the work of the engineer.

Introduction

Clearly, such a treatment as this cannot be exhaustive. Even though very limited in what it attempts, it is necessarily general in treatment. It is hoped that it will not be misleading, but it is too much to hope that none of its statements will be at variance from, or even contradictory to, that which is good law in some of the forty-nine different jurisdictions within the continental United States. It is assumed that, charitably and with good common sense, the reader will remember this fact; and also that, to be on safe ground, he must be ably advised on any given point concerning the law in the jurisdiction in which he is concerned. That the law of all other jurisdictions on that point might be otherwise would probably not then be material.

Note.—Published in May, 1941, *Proceedings*.

QUALIFICATIONS OF A SURVEYOR

Let the reader consider a hypothetical surveyor, Mr. S, as he makes his preparation for his tasks, and go with him through some of the situations that he may be required to meet.

In most of the states of the Union there are now statutes providing that any person who is to do boundary surveying (or, as it is more commonly but less definitely called, "land surveying"), in the sense that he is to be in responsible charge of a boundary survey, must be registered or licensed by an examining board. These statutory requirements vary considerably from state to state, but they are easily discovered by referring to the code or the general laws of the state in question. Let it be assumed that if Mr. S is to practice in a state that has registration laws he has convinced the Board of Examiners that he is qualified to the extent that the statute and the Board require, and that he has been duly registered or licensed to practice.

Thus, the representatives of the state have in effect pronounced Mr. S to have at least the minimum personal and professional qualifications that should permit him to practice. What degree of care, skill, and judgment may a prospective client properly expect of him; and what may be the consequences if he fail to measure up in these respects to the requirements of some job that he may undertake? The courts answer this question by quoting the phrases that have long been used in the law to define that standard of conduct which separates negligence from due care: He must "exercise that degree of care which a skilled civil engineer of ordinary prudence would have exercised under similar circumstances."[3] The engineer will probably wish for a more specific, more tangible criterion that could be generally applied; but he will seek in vain. This standard must be used and interpreted in the light of the circumstances of each situation. In Ferrie vs. Sperry[3] the court says,

> "* * * it was important that the jury should know what such an ordinarily prudent engineer would do under the circumstances of this case. Might he simply examine the land records and muniments of title, and observe the fixed monuments and evidences of present occupancy and ownership; or was he bound to scour the neighborhood to learn whether there had been adverse occupancy and claims of ownership of any part of the premises covered by his client's deed by others than the latter's predecessors in title appearing of record? * * * The jury would not know, unless informed by evidence, and such evidence was admissible."

Thus must the question be resolved if it finally come to a court—by expert testimony of those who profess to know what should be done.

DUTIES AND LIABILITIES OF THE SURVEYOR

The present interest, however, is in having Mr. S do whatever he should do, and in keeping him out of court. Mr. S, then, should make as thorough an examination of all reasonably available sources of information as circumstances seem to permit—and err a little on the side of safety, in diligence of search. This applies to matters of record, to evidences of boundary or of occupancy to be found on the ground, and to any other items of information that his eyes or his ears can discern. He must then pursue his field work and computations by such methods as will secure a precision appropriate to the job, and will eliminate the possibility of there remaining that bugbear of all engineers, a mistake. He should make very clear to his client the situation that he finds, in order that, if necessary, the client may use his own judgment in seeking legal advice as to the significance of conditions of occupancy, conflicting claims, and other matters that may override metes and bounds in fixing the lines.

---

[3] Ferrie vs. Sperry, 85 Conn. 337, 82 A. 577.

True it is, the owner wants and expects to have the proper boundaries marked and reported to him, and does not want a list of conflicting items of evidence; and to the credit of the judgment of surveyors it may be said that that is what he usually gets. It is this "judicial function" of the surveyor (thus so aptly termed by Mr. Justice Cooley, of the Supreme Court of Michigan) that calls for experience and sound legal judgment, as well as engineering ability, on the part of a surveyor.

Suppose Mr. S fails to measure up to this required standard of care and skill. It has been generally held that he is answerable in damages to his client for the loss or injury that results from such failure—at least for any loss coming from a use of the land in a manner known to the surveyor to be contemplated at the time of the survey. A surveyor has been required to pay the cost of moving an apartment building, built to the line which he had marked, back some five feet to the true line.[4] The difficulty in that case was that of a mistake in measurement,—which is undoubtedly a clear failure to use due care. The surveyor in this case was not relieved of his burden (to a cost of some $1,267) because he had charged only $12 for the survey—a rather impressive commentary on the undesirability of cheap surveys, from the standpoint either of the surveyor or of the client. The custom of giving a certificate of accuracy, for which a higher fee was charged, was found "wholly immaterial" in this case.

It has been held that if a person is employed as a municipal official (for example, a city engineer) and does work for private persons as a function of his office, he is liable to them only in case of loss from his negligence or fraud; but that if a person works in the capacity of a private practitioner he is liable as well for loss resulting from want of skill.[5] Cases in other jurisdictions seem to indicate that the more general rule is that a surveyor undertakes to bring reasonable skill and knowledge to his work, be it done in either official or private capacity, and that he will be liable for loss resulting to his client because of his failure to do so.[6] The municipality, however, is not liable if its engineer does work erroneously at the request and for the benefit of a private person (in the case cited, setting stakes erroneously to show street grades in front of a house lot); even though he be bound, in his official capacity, to do such work upon request.[7]

---

[4] Taft vs. Rutherford, 66 Wash. 256, 119 Pac. 740, 38 L.R.A. n.s. 1043.

[5] McCarty vs. Bauer, 3 Kan. 237.

[6] Highway Commissioners vs. Beebe, 55 Mich. 137, 20 N.W. 826.

[7] Waller vs. City of Dubuque, 69 Iowa 541, 29 N.W. 456.

It is believed that the duties and liabilities to his client of a surveyor who has been registered or licensed to practice do not differ from those of an unlicensed practitioner in a jurisdiction where license is not required. Of course, one who is licensed but is subsequently found incompetent may be prevented (by such process as is provided in the statutes of the state in question) from continuing to practice, or he may have his license revoked.

SURVEYOR'S RIGHT OF ENTRY

Now, suppose that Mr. S, duly advised as to the care to be used, is proceeding with his survey. It may be practically necessary for him, either in actually running out the lines or for the purpose of reaching control monuments to which to refer his survey, to go on other land than that of his client. Surveyors regularly do this, but have they any right to do so?

If the surveyor is conducting in a reasonable manner a survey for an undertaking directed or authorized by act of the legislature, and if "the entry is reasonably necessary, and * * * is but a temporary one, and accompanied with no unnecessary damage," there is no trespass.[8] It is generally held that a body having the right of eminent domain in the furtherance of some project may, without payment of compensation, enter upon private land to make preliminary surveys therefor, and that such entry is not a trespass; and the statutes of some states so provide. Under such rulings, surveys for highways, for railroads, and for other improvements have been made; and the officials of New England towns have performed their duties of periodically "perambulating" their boundaries.[9] Of course, compensation must be made for any actual damage done, and any excessive or unnecessary damage will be enjoined.[10] In at least one case it has been held that where the state's officers (the state engineer and those working under his direction), in making a survey directed by the legislature of a disputed boundary line of certain counties, exceeded the amount of damage that was reasonably necessary, the state was not liable for the excess damage but the state's officers were.[11] In this case the damage complained of consisted in cutting through plaintiff's woods a "slash" 3½ miles long and from 5 to 25 ft wide, for the purpose of establishing a base line. A referee in the case found that the method used was proper, and the best for the purpose, and that the work was skilfully and carefully done. The damage amounted to about $500. It should be mentioned that in this case both the referee and the lower court had found for the defendants (the surveyors) and that in the Appellate Division there was a strong dissenting opinion.

In the absence of any official mission or the possession of any official character, a surveyor who enters the land of another without permission is as much a trespasser as any other intruder would be. The action of trespass will lie even though no actual damage be done to the land or to any of its appurtenances.[12] Perhaps it may be apt to remark that, again, it is much to the credit of the ability of surveyors to "get along" amicably with those on whose land they almost necessarily trespass, that there are in the books very few cases of actions of trespass against surveyors, or because of the mere act of surveying.

Dill. Mun. Corp. 4th Ed. Sec. 614.
Edwards vs. Law, 71 N.Y.S. 1097, 63 App. Div. 451.

[9] Fox vs. Western P. R. Co., 31 Cal. 538.
Burrow vs. Terre Haute & L. R. Co., 107 Ind. 432, 8 N.E. 167.
Brigham vs. Edmands, 7 Gray (Mass.) 359.

[10] Dancy vs. Alabama Power Co., 198 Ala. 504, 73 So. 901.

[11] Litchfield vs. Bond, 186 N.Y. 66, 78 N.E. 719.

This is the situation under the common law, but in some states legislative enactments have brought a modification. As an example, Section 2586 of the Public Laws of Vermont (1933) is quoted:

> "In cases wherein the title to lands, tenements or hereditaments may come in question, the practical surveyor with the necessary assistants, employed by any of the parties to such disputed title, may enter upon such lands or real estate, or other lands, for the purpose of running doubtful or disputed lines and locating or searching for monuments and ascertaining and deciding the lines and monuments of a survey, doing as little damage as possible to the owners of such lands."

Laws are now appearing on the statute books of a few states giving to engineers or surveyors the right to enter upon private land, whereon is a control survey station, for the purpose of using the station for engineering or surveying purposes. The laws usually require that no unnecessary damage be done, and that any anticipated damage be paid for in advance.[13]

A conclusion, drawn from all the foregoing and from the common experiences of surveyors, for the guidance of Mr. S, may well be summarized somewhat as follows:

The survey of a boundary line will almost inevitably require going on other lands than those of the client. Ordinarily, if care is used to cause no appreciable damage, no objection will be raised by the owner or occupant of such land; and if and when such objection is raised a frank explanation of the surveyor's need of permission to enter, a sincere promise of due care, and an explanation of the disinterested and non-partisan character of his work and conclusions will often secure the needed permission. Such entry, however, cannot properly be forced unless the surveyor is acting in an official capacity or for a legally-authorized undertaking; or unless it is under such a statute as that just mentioned. The invasion should be as brief and unobjectionable as practicable, limited strictly to the purposes of the survey. No reasonably avoidable damage should be done, and any unavoidable damage should be explained and compensation made.

FINALITY OF A SURVEY

As Mr. S proceeds with his survey he may reach very firm and, in his opinion at least, very well-founded opinions as to where the lines with which he is concerned are, or should be. It is usually expected by his client that such will be the case, and that monuments of some kind will be set to represent such conclusions. However, Mr. S may find that his conclusions disagree from those of some other survey or from evidences of occupancy and use. May he, if he is "sure" he is right, "establish" the boundary? The same question is sometimes put differently by a client: "Is your survey 'legal'? Will it 'hold'?" The answer probably should be that no survey, unless it be of an original and official character such as were the original surveys of the United States Public Lands, is "legal" in the sense in which people use that term in this connection; nor will it necessarily "hold" without the occurrence of one of two things: (1) The acceptance of the result by those whose interests are affected, or (2) a decree of court that the survey represents the proper solution of the boundary problem involved.

---

[12] Dougherty vs. Stepp, 18 No. Car. (1 Dev. & Bat. Law) 371.

[13] An excellent example of such a law is included in Chapter 628 of Laws of Maryland 1939. The part of that chapter to which reference is here made will become Sections 32 to 35, inclusive, of Article 91 of the Annotated Code of Maryland (1924 Ed.).

No modification of this statement is to be made because the surveyor may possess some official character, such as that of a city or county surveyor, nor because that which such a surveyor has concluded is sanctioned by his superiors (the county commissioners, for example). He has no more authority to conclude a matter of boundary than has a private surveyor,—or a blacksmith. Property rights must be settled by those who own them or by the courts. The Michigan court has well said,[14]

> "It is quite manifest that in this case there seems to have been an idea that the ex parte action of surveyors and commissioners was entitled to credence and authority upon the true lines and the fact of encroachment [of a fence and buildings alleged to be within a highway]. Neither of them can affect vested rights or settle controversies. They may be useful witnesses, when they speak of matters with which they are familiar, but they have no greater right than anyone else to determine starting points or boundaries. * * * The rash and vexatious acts of local officers not under the process of law are fruitful sources of bad blood and litigation."

(Since the boundary of a highway has been mentioned let the caution be noted that cases in which boundaries of highways are concerned are ordinarily excluded from the effect of the doctrine of acquiescence or that of adverse possession.[15])

Now that the legal situation has been outlined, let the statement be made —once more to the credit of surveyors in general—that, as a practical matter, many a boundary dispute has been settled by surveyors, many boundaries have been "established" by them; and may such continue to be done. In honest, competent hands, this is one of the most practical, most useful results of the exercise by the surveyor of his unofficial "judicial function."

ARBITRATION

Now let it be supposed that, at the end of his work over some boundary, Mr. S does reach a conclusion which differs from that of some one else, or to which not all items of evidence—or "calls"—agree; or perhaps he is forced to the conclusion that it would be disproportionately expensive, or even practically impossible, to execute surveys that would enable any honest surveyor to say, "There are the stakes which with reasonable certainty and precision mark the line." It may often be true, in such a situation, that it will be possible to say, with relatively small limits of variation, approximately where the line is. Evidences of occupancy might accomplish that, or the differing conclusion from another survey may not represent a large difference. Mr. S's best service, in the interest not only of his client but of all who are concerned, may now lead him to suggest that the best results, both from the standpoint of property rights and also with reference to the amicable relations of all concerned, will be reached by compromise or by arbitration. If interested persons will either come to an understanding of all the conflicting elements involved and then hit upon and accept a solution, or if they will let the surveyor propose a compromise solution, with the reasons therefor, and then accept it, the Gordian knot will be cut,—and the chances are good that all will be happier than at the reaching of a conclusion in a court of law; for, after all, the decision of a court would have to be based on evidence, and it is unlikely that the court would have any more evidence, or have it presented with less bias, than that now in the possession of the surveyor. No suggestion is here made that any substantial, well-founded rights of a client, properly enforceable in a court, should be recommended for surrender; it is believed that the proper setting for the procedure recommended has been made clear. Obviously, to function acceptably in the rôle suggested, Mr. S can use all the legal and engineering training and experience and judgment at his command. To carry the matter to its best conclusion, as a competent and fully-informed court would do, will be another instance of his exercise of his judicial function.

---

[14] Gregory vs. Knight, 50 Mich. 61.

[15] Langle vs. Branch, 193 Iowa 140, 185 N.W. 28. Subject is discussed in 6 A.L.R. 1210.

What must be done to make such an acceptance of a compromise solution binding? How should it be perpetuated?

With reference to the first of these two points, it seems clear that nothing further than the parol—oral—agreement of the owners concerned is needed to conclude the matter and to make their agreement binding upon them and upon their subsequent grantees. This is not a situation in which, under the statute of frauds, a writing is necessary to make the agreement effective. In a brief, but clearly-expressed, case[16] the Supreme Court of Arkansas has said,

> "This court has held in accord with the weight of authority that, where there is doubt or uncertainty or a dispute has arisen as to the true location of a boundary line, the owners of the adjoining lands may, by parol agreement, fix a line that will be binding upon them, although their possession under such agreement may not continue for the full statutory period."

The Supreme Court of the United States has held[17] that such an agreement is "not a contract for the sale or conveyance of lands. It has no ingredient of such a contract." Adjoining owners hold up to a boundary thus fixed by consent by virtue of their title deeds, not by virtue of a parol transfer between themselves.[16,18]

---

[16] Robinson vs. Gaylord, 182 Ark. 624, 33 S.W. 2d. 710.

[17] Boyd vs. Graves, 4 Wheat. 513, 4 L.Ed. 628.

[18] Cutler vs. Callison, 72 Ill. 113.

Such an agreement to fix a boundary line is void if the owners know or if one of them knows that the agreed line is not the true line.[19] It is then in effect a transfer of land, or perhaps even a fraud on the part of the one who knows. However, that the line could be ascertained by an expensive survey, the cost of which the owners thus avoid, does not prevent the uncertainty that must exist to make the agreement valid—and valid "even though the true line should afterward be ascertained."[20,21]

It may be that the parties will prefer, rather than to try to agree upon a location themselves, to submit the question of boundary to arbitration. Still assuming that the arbitrator is an honest and a competent surveyor, that may be the very best solution. That it is a valid one is amply supported by decisions.[22] It is not necessary that the agreement to do so be in writing[23]; although, to prevent misunderstanding, a writing may sometimes be desirable. When a writing is used, it should be carefully drawn, and it must be taken to be the entire basis of the submission to arbitration. No parol modification would be effective, under the statute of frauds,[24] or the parol evidence rule.

The award, resulting from an arbitration conducted in accordance with the terms of the submission, is valid and conclusive.[25] It cannot be impeached because of an honest mistake of judgment on the part of the arbitrator.[26]

This fact, and the aforementioned fact that a location agreed upon will stand even though subsequent developments show that it was not the true line, are only corollaries of the elementary and fundamental principle of boundary law that a boundary once authoritatively established and adopted remains in that place, regardless of mistakes of measurement or of judgment made in arriving at that location. This principle is too thoroughly established and too well known to require citation of authority or discussion here. It is comparable in importance to, and is directly connected with, the fundamental rule for interpretation or construction of land descriptions and for search for land boundaries—namely, that which is to be accomplished if possible is to ascertain and to carry into effect the intent of the parties. To effectuate these fundamental principles, all rules and all "order of calls" are enunciated, and to them all such rules must yield.

All that is absolutely required to be done to make a location by agreement or by arbitration effective,—to perpetuate it,—is to describe the boundary with certainty.[27] However, as a surveyor, Mr. S should know that to provide a permanent remedy, to prevent a recurrence of the trouble, the line should be adequately and "permanently" monumented and platted, and the plat should be recorded with written, signed, and acknowledged acceptance of that which is shown thereon, or accompanied by a written submission to arbitration and a certificate by the arbitrator that the plat shows the result of the award.

[26] Rottman vs. Taft, 204, N.W. 585, 187 Wis. 558.

[27] Giddings vs. Hadaway, 28 Vt. 342.

Now, lest Mr. S might (from the emphasis thus far laid on agreement or acquiescence) think that the author is saying that such acquiescence concerning another boundary than the original surveyed line destroys all significance of the latter, two points should be kept in mind:

The first is merely a matter of interest to be noted in passing; namely, it has been held[28] that the conveyance of land by government subdivisions, without any representation of quantity, conveys only that portion included within boundaries acquiesced in for more than the period of the statute of limitations, and visibly marked, even though it is less than the full area of such subdivisions.

The second point, of more general consequence, is that although such acquiescence or agreement in a boundary line is binding on the parties thereto and on those claiming under them[29] (grantees, heirs, etc.) only such persons are bound by the acquiescence or agreement.[30]

This conclusion has some implications that would lead out of the immediate field of the present discussion; but the point to be noted here is that, although agreement, acquiescence, or adverse possession may have taken away from the original location of a section line, for example, its character as a boundary line between the contiguous parcels, it may still be essential to locate the original position of the section line and of the section corners thereon as sources from which to work in locating other lines or corners. Even though the significance of the first lines as immediate boundaries may have disappeared, they are just as effective (if they can be found) as they ever were in every other respect.

THE SURVEYOR AS AN EXPERT WITNESS

It is to be hoped that Mr. S can conclude for his client the questions of boundary with which he may be concerned without the necessity of the latter becoming involved in an action in court. There are some situations, however, in which only a court can settle the matter properly. In such a case Mr. S should be able to be of material assistance to his client's attorney; and this he can do better if he has some knowledge of the law concerned. Attorneys, especially those in general practice, are not always entirely familiar with matters of boundaries, with the engineering terms involved, with the practicability or the difficulty of accomplishing, in special situations, things which seem theoretically possible. It should not disturb the professional pride of a lawyer to review his trial brief with the surveyor; and the writer has known of cases in which, as he believes, the procedure and possibly the result could have been improved had that been done. Ordinarily the surveyor will be used as an expert witness. That this may be done effectively requires that the examining attorney and the prospective witness go carefully over the matter beforehand. The witness may well explain, first (if it is not already known to the attorney), just what the witness' testimony should show. Questions can then be framed which will clearly and expeditiously bring these facts before the court. If the surveyor listens carefully during the trial, especially as other surveyors give their testimony, he can frequently be of material help in catching points or suggesting questions of a technical nature. None of this savors in any way of shady practice or of any variation from the truth. No reputable attorney will ask or expect a reputable engineer to become involved in any "sharp" practice to gain a technical advantage, nor to vary from the truth as he sees it in giving his testimony.

It may be worth while to inject here the statement that even in states which have statutes providing that no surveys shall be legal evidence unless made by a county surveyor or his deputy, or by the United States or by the state, it has been held that such statutes do not preclude the admissibility of testimony of a competent private surveyor concerning a survey made by himself, or concerning a plat of it that he has made.[31]

It is clear that, in giving testimony, a surveyor may refresh his memory by referring to his field notes or to a plat made from his notes. This is true even if the survey or the plat were not made in all respects in accordance with a statute providing methods therefor.[32]

Admissibility of Plats and Field Notes

The following excerpt from Corpus Juris Secundum[33] states concisely the general situation concerning the admissibility as evidence of maps and plats. The citations here given are only a few of those available:

> "As a general rule, maps or plats of surveys are admissible in evidence.[34] These include maps or plats made by the county surveyor or other official surveyors[35]; plats of unofficial surveys when made by a qualified surveyor[36]; maps from the land office,[37] although made subsequent to the beginning of the action[38]; and maps made by order of the state land board. Likewise, plats and maps attached to and made a part of deeds or grants or referred to therein, either expressly or by clear implication,[39] maps which have been recognized as correct by a former owner of the land,[40] and ancient

maps and plats when duly authenticated,[41] are admissible to prove a disputed boundary. A map or plat referred to in the testimony is admissible as explanatory of it.

"In all cases the map or plat must be verified or authenticated,[42] and in the case of a surveyor's plat proof offered that the surveyor making the same actually traced the lines on the ground as depicted."[43]

However, in one case[44] it was held that

> "* * * plats and surveys attached to certain deeds and made by reference a part thereof were properly admitted in evidence with the deeds, notwithstanding the attached documents were not proved by the surveyor nor their correctness otherwise established. * * * Aliter [It would be otherwise] if the plats and surveys had not been made a part of the deeds themselves."

With reference to the plats or field notes of surveyors now deceased, one court[45] has held that:

> "* * * ancient plans of lots, showing the original lotting and boundaries assigned, also ancient minutes of surveyors, which were made by capable independent surveyors, having no interest to misrepresent, and which have been preserved, and are produced from reliable sources, may likewise be used on trial, when the boundaries of lots to which said surveys refer come in question."

To the same effect are cases from other jurisdictions.[46]

Some states have by statute made the matter relatively clear. An example is the following section from the Iowa Code:

> "11295. *Field notes and plats.* A copy of the field notes of any surveyor, or a plat made by him and certified under oath as correct, may be received as evidence to show the shape or dimensions of a tract of land, or any other fact the ascertainment of which requires the exercise of scientific skill or calculation only."

In situations quite analogous to those affecting the introduction in evidence of plats, the field notes of an authorized survey, when duly authenticated, are at common law admissible.[47] Also, at common law, the field notes of a deceased surveyor are admissible[48]; but at least one court has held[49] that a statutory procedure, recently enacted, under which county surveyors' field notes may be admitted, abrogates the common law which admitted the notes of surveyors, either public or private, and that therefore all other field notes than those of county surveyors are excluded. This would seem to be an undesirable result.

[49] Peck vs. Molhoek, 228 N.W. 721, 249 Mich. 360

The older practice has been to take field notes in a bound book, and it is undoubtedly that form of field book which has usually been introduced in evidence. Mr. S may prefer a loose-leaf field book, and a question may arise in his mind as to the admissibility of notes taken on such loose sheets. Whatever may be one's opinion of the judgment of Mr. S if he decides to use loose sheets, even in some form of "binder," for field notes, it is still probable that if the sheets are properly identified and authenticated they would be admissible under the same circumstances that would admit a bound book. The writer knows of no case directly in point. The practical difficulty of authenticating and handling half a dozen separate sheets bearing the notes of a survey, as compared with the corresponding use of a book, would seem likely to produce some annoyances and danger of loss. The foregoing opinion concerning admissibility is based, by analogy, on modern usage concerning office records. By statute in some states, and by court decision in others, loose leaves[50] or cards[51] bearing office records are admissible as evidence when properly identified.

It is true that loose, miscellaneous memoranda have generally been excluded, but "the admissibility or inadmissibility of such entries would appear to rest more on their form than on the nature of the book in which they are made."[52]

DEFINITION AND OWNERSHIP OF FIELD NOTES

It has seemed that not all usages are quite consistent as to what is meant when the term "field notes" is used. Field notes are defined in Corpus Juris as "Notes made by the surveyor in the field while making the survey, describing by course and distance, and by natural or artificial marks found or made by him where he ran the lines and made the corners."[53] "Words and Phrases" uses the same definition, referring to the same case therefor; and with this definition a surveyor should have no quarrel. However, in spite of this plain statement in this case, apparently taken by both authorities quoted as the best available definition of field notes, some usages seem to refer to a description subsequently "written up" from the notes which were actually put down at the time measurements were made or objects were observed. Some substance is lent to this view by an inspection of the books said to contain the "original field notes" of original government surveys of the public lands. To make a very conservative statement, these books, and the neatly ink-written narratives that they contain, do not seem likely to have been with the surveyors in the field under some of the conditions of weather and work described therein. The terms "field book"[54] and "field notes" are sometimes applied to books and contents that are obviously office (usually a public office) records.

These observations are made in reference to suggestions sometimes heard that the field notes of a survey should be turned over to the client upon completion of the work as part of that for which he presumably has paid. It is the opinion of the writer, and of others with whom the matter has been discussed, that this would not be the best arrangement, either from the viewpoint of the surveyor or from that of his client. It is the opinion of the writer that Mr. S should turn over to his client, in the most useful form practicable, all the essential information that has been accumulated at the expense of the client. The most useful form (in addition to whatever physical evidences of the work are left on the site) will probably be a plat. A written description of the boundary may sometimes be useful, and to this some persons might give the name "field notes." A more probable label would be a "survey," which name seems to be used indiscriminately to refer either to the work done or to the report of such work in the form of a description.

[53] State vs. Palacios, Tex. Civ. App., 150 S.W. 229, 236.

[54] Neill vs. Ward, 153 A. 219, 103 Vt. 117.

This plat or other report should be as complete as circumstances will permit. It should be sufficient to enable any qualified person to identify the land or to recover an obliterated bound at any time in the future. The withholding of any essential data for the purpose of insuring reemployment on any future work in the vicinity cannot be too strongly condemned; but the field book—the book used in the field at the time the work is done, and in which the data are set down, usually in pencil, as they are observed—may better stay in the hands of Mr. S. It is quite probable that these notes will be in a tabulated form, in which they would be of little use to a client who was not himself familiar with survey work and notes. They probably contain data concerning random traverses, and the like, which would only be confusing to him. Moreover, cases which have been cited herein indicate, incidentally, that field notebooks are frequently found in the possession or among the effects of those who took the notes. The writer has neither read nor observed in his own practice anything that would lead him to believe that there has been, or is, any custom of turning field notes of private surveyors over to their clients; nor has he seen anything in statute or reported decision to cause him to think that it is expected—let alone required.

Of course, the terms or circumstances of the engagement of an engineer, either as a public official, such as a county surveyor, city engineer, etc., or as an employee in a private office, often make it clear that the notes he takes are not his private property but belong to the office. The remarks that have been made concern the engagement of a private surveyor or engineering firm on private work for a client.

SURVEYOR'S REPORT TO HIS CLIENT

One of the final matters with which Mr. S will be concerned in a survey is the furnishing of an adequate description of the land surveyed as one of the chief elements of his report to his client. The two purposes which this description must serve should be constantly kept in mind:

(1) It must make convenient and certain the identification of the tract of land for the purpose of tracing title; and

(2) It must be sufficient to enable any competent engineer to restore conveniently at any future time a bound (or all the bounds) which may have been obliterated.

For the first purpose, in order that it may be incorporated in a deed, a verbal description, giving general location, and perhaps adjoiners, is essential. It should be as brief as practicable, should be such as may conveniently be used over and over in successive instruments, each of which should refer to a preceding one; and, as an item of paramount importance, it should incorporate a plat by referring to it so as to make the plat a part of the deed description. That the complete description given on the plat will then determine the boundaries of the land conveyed is now too well settled to require authority for the statement here.[55] For the most part the cases cited in discussions of this matter are situations in which some special point had caused the raising of a question; for example, it is immaterial by whom the map was made[56]; or the plat was not acknowledged or recorded[57]; or it was invalid.[58]

Needed for the first purpose mentioned, but absolutely essential in many cases for the second, is the incorporated plat. It is a matter of common knowledge and observation that graphical descriptions are often not only much more convenient than verbal ones, but much less likely to be misunderstood. To this rule land descriptions are no exception.

Mr. S has been assumed to be a competent engineer; therefore, one need not here review the specifications for a satisfactory plat,—other than the fundamental requirement expressed under Purpose (2). It should be so numbered or titled as to be referred to conveniently in the verbal part of the description; and it should be certified or acknowledged by the surveyor, and of course made a part of the record.

SURVEYOR'S FINAL OBLIGATION

Finally, with reference to the service which Mr. S should render his client, it may be stated that he should do his work so that it is unlikely that that particular job will ever have to be done again; and, paradoxically, it should be so done that it could be retraced conveniently by any competent engineer —stranger to the locality though he may be—at any time in the future. The first of these two requirements can best be attained by the use of distinctive and enduring monuments. To economize by setting wood stakes or other cheap monuments to perpetuate a survey is indeed being "penny wise and pound foolish." From a legal, engineering, or just good common sense standpoint, the best advice that can be given to a client in this respect (and all too often the client must be "shown") is to add to the cost of the survey enough to monument it well.

Concerning the second requirement—that of adequate description—beyond that which has been said, it is desired to emphasize but one point: It is sometimes true that plats which are complete in themselves are only inadequately located with respect to adjoining land. Until very recently no one satisfactory means of stating or showing such relative locations has been generally available. Now, with state plane coordinate systems devised for every state and permanently connected with the national control system of triangulation, such a means is at hand. As time and surveys go on, this means is becoming accessible to more and more land. Wherever this control is available, practically and economically, it should be used. Whenever practicable the plat should show in terms of coordinates in the state system the positions of one or more monuments on the boundary, and of one or more monuments on a control survey. Directions should then be stated in azimuths, referred, of course, to the same system. A statement on the plat should make it clear that this has been done. Statutes have been enacted in some states making definite the fact that such is an adequate description; but it is believed that, in the absence of any statute, the common law which would be applied in any state is clear that such a description is good. There are many decisions to the effect that a "deed must contain such a description * * * as will enable the property to be readily located by reference to the description"[59]; and also to the effect that "if the description of the land conveyed in a deed is such that a surveyor, by applying the rules of surveying, can locate the same, such description is sufficient * * *."[60]

---

[55] See 9 C.J. 180, sec. 50.

[57] Johnstone vs. Scott, 11 Mich. 232.

[58] Young vs. Cosgrove, 49 N.W. 1040, 83 Iowa 682.

It is for the quality of description specified by these quotations that the writer pleads: Such a description as "a surveyor"—any surveyor—can effectively use "by applying the rules of surveying"; not something that merely furnishes an opportunity for the exercise of ingenuity in the solving of a puzzle. The proper use of the state plane coordinate systems, now officially approved for this purpose by both the Society and the American Bar Association, is, in the opinion of the writer, the best means thus far made available for assuring the certainty and the permanence that are required.

DISCUSSION

E. F. CHANDLER,[61] M. AM. SOC. C. E.—Special commendation is due this paper because it brings so definitely to attention one very important feature of the work of a land surveyor making field measurements to determine the proper location of doubtful or disputed boundaries. This is the fact that if the surveyor is not merely careful in his surveys but also fairly informed on a certian line of legal questions he is often able (unofficially, but by willing consent of both parties) really to fulfil a judicial function and bring about fairly harmonious agreement between parties who might instead have resorted to costly hearings in court.

The nontechnical purchaser is quite likely to think, and can easily be misled to believe, that his deed gives absolute and complete legal title to the lengths and acreages specified by it, which of course is not invariably true.

For example, careless work in the early surveys many years ago may have vitiated all the data recorded in them. A striking case of this came before the writer in his own early experience, in south central Wisconsin, where there was a dispute concerning boundaries between adjoining land owners, each of whom had a deed of very convincing prima facie appearance. In both cases, dimensions were taken directly from the plats of the original government contract surveyor, who had staked off the townships and sections there in some year of the late 1840's. About fifty years later, the writer retraced a series of the lines, and was fortunate enough still to find indisputable evidence (witness trees, bearing trees, etc.) at almost every adjoining section corner and quarter-section corner. On one line between corners (east and west in Section 6, and therefore not assumed or reported as a precise mile) a so-called mile was found to be actually about 900 ft less than the figures certified for it by the original contract surveyor. No surplus was in any adjoining section that could by any possibility be obtained on the plea of an alleged mistake or blunder by the original surveyor in accidentally witnessing some trees at an unintended point. In this case, however, the land had been so long occupied without objection that it was easy to make the most injured claimant realize that, although his quarter section was really 900 ft narrower than the distances alleged in his deed, it would be a useless expense to bring any suit or to attempt to reclaim something that actually did not exist.

To avoid stirring up needless claims or disputes based upon present-day failures of tracts to fit precisely the reported metes and bounds certified by the surveyors of earlier days (some of whom were quite hurried, careless, and inaccurate, and some even worse in framing up semi-fraudulent description), the land surveyor now should keep clearly in mind the usual rule for accepting priority of calls in the early surveys, which holds (except in special or unusual cases where there is extra evidence supporting one or another of the conflicting items)—namely, the general rule that definite unchanged landmarks, monuments, or permanent stakes and fences outweigh all other evidence; lengths and distances have less weight, but outweigh directions or bearing; bearings are good evidence only as compared with areas; and areas have little or no value in fixing boundary-line locations, being merely corroborative unless the other calls are lacking.

---

[61] Prof., Civ. Eng. and Dean Emeritus, College of Eng., Univ. of North Dakota, Grand Forks, N. Dak.

The author refers briefly to another principle that the surveyor must constantly remember if he does not wish to encourage his client in useless disputes—the doctrine of "adverse occupancy." Briefly worded, in most states undisputed continuous possession "under color of title" through ten years gives the occupant indisputable ownership; or even without color of title he gains ownership in twenty years. In different states there are variations, so that in some localities even half this time (five years, or ten years) is sufficient; there are different technical exceptions in different places (such, perhaps, as the law not beginning to hold against minor owners until they reach the age of twenty-one, and never holding against the general public, but merely against individual owners, etc.); and, of course, the occupancy must have been absolutely undisputed, without legal objection at any time in the entire period. The surveyor must, perforce, keep in mind the effect of that statute of limitations, whatever its precise form may be in that jurisdiction, and must not unduly encourage his client to hope to gain or regain, merely by mathematical measurements, the possession of real estate, the ownership of which has really been lost by years of neglect.

If the surveyor is careful, however, is fairly accurate in the engineering work of his surveys, has a well-founded general idea of the legal principles attaching to them, and has good judgment in avoiding the appearance of prejudice or bias, he will usually find his recommendations accepted (perhaps rather unwillingly, but because seeming the most reasonable to both sides) without any need for final resort to courts of law, or to the vote of a jury of twelve men, none of whom is likely to have more than the merest superficial knowledge of such matters.

If a case does actually come to court trial, the evidence of a surveyor as an expert witness on matters to which he can properly testify should be practically incontrovertible. Furthermore, as stated by the author, if he does not claim greater proficiency in legal knowledge than the lawyer himself, the lawyer probably will be glad of his advice or assistance on the technical sides of the question. If the case is quite important, the lawyer may even (as has repeatedly befallen the writer) ask the surveyor-engineer to make for him the preliminary draft of the engineering part of his brief.

HARRY RUBEY,[62] M. AM. SOC. C. E.—This is a valuable paper by the author on the professional aspects of a subject too little understood by engineers. The Society is indeed indebted for the many references that accompany the paper—references that most engineers would otherwise overlook. From the wide range of possible discussion of the paper, the writer will attempt only to emphasize the professional nature of the work, as distinguished from the subprofessional status ordinarily assigned to it.

Too often the subject of boundary surveys is discussed and practiced as a distinctly subprofessional activity. The author is entirely correct in implying that a highly professional engineering judgment, often involving a considerable legal knowledge, is required for boundary surveys that fall outside of a simple routine.

---

[62] Chairman, Civ. Eng. Dept., Univ. of Missouri, Columbia, Mo.

The actual surveying—that is, the making of measurements and calculations—frequently might be classified as subprofessional; but when the engineer so engaged is called upon to exercise legal knowledge and judgment in connection with surveys, the work takes on a professional character, and in many cases may become highly professional.

Although the private engineer possesses no formal legal status other than that of expert witness, actually and informally he must advise his client and conduct his surveys in accordance with accepted legal principles. In many cases, the engineer must cooperate on a definitely professional basis with an attorney, both in the preparation of a case and in the negotiations or court proceedings connected therewith. From the moment the engineer is approached by a client regarding a boundary survey, his advice and action must be based on sound legal knowledge and professional judgment.

When it is realized that the interests of the client, the engineer, and the community are best served by securing the facts, by studying the case, by definite solution from a survey, by settling the controversy through agreement or by arbitration, and perhaps finally by court action, the professional nature of the engagement becomes apparent.

Another definitely professional phase of this subject in which the Society cooperates with the American Bar Association was stressed in 1941.[63]

It would be most valuable if the author could give in some detail the engineer's ethics, techniques, and procedures in the matters of arbitration and expert testimony.

All too few qualified engineers and attorneys are available for professional boundary survey assignments, and the published information and discussion of the matter are entirely too limited.

WILLIAM H. RICHARDS, JR.,[64] M. AM. SOC. C. E.—Professor Holt renders a service to those interested in boundary surveys in his discussion of the duties and responsibilities of surveyors when engaged in recovering and establishing boundaries of land. His paper indicates the combined technical and legal character of the land surveyor's work and demonstrates the necessity for some knowledge of the law on this subject and of legal procedure by the civil engineer who engages in this field of activity.

Under the heading "Definition and Ownership of Field Notes" the author observes that field notes, although defined in Corpus Juris as "Notes made by the surveyor in the field while making the survey," also, apparently, under some usages, refer to a description subsequently written up from the notes actually taken in the field. He mentions in this connection the "original field notes" of the public land surveys.

There is a very definite distinction between the notes and data taken by the private surveyor during the progress of his field work and the official field notes of the public land surveys. The current edition of "The Manual of

[64] Cadastral Engr., Gen. Land Office, Div. of Surveys, Washington, D. C.

Instructions for the Survey of the Public Lands of the United States" contains the following statement in this connection: "Section 542 The initial notes are kept in pocket field tablets. The final field notes for filing are transcribed from the field tablets, and are typewritten upon regulation field note paper."

The 1881 edition of the manual of instructions contained the following statement relative to field notes:

> "From the data thus recorded [in field tablets] at the time when the work is done on the ground, the deputy [surveyor] must prepare true field notes of the surveys executed by him, in the manner hereinafter prescribed, and return same to the surveyor general, together with the required sketches, at the earliest practicable date after completion of his work in the field."

Such final or true field notes, when duly certified by the surveyor, approved by the supervisor of surveys (formerly by surveyor general), and accepted by the commissioner of the General Land Office, are the official field notes.

The actual running of the lines of a survey in the field and the recording of the notes are not alone sufficient to constitute an official survey. Until all the requirements as to approval are complied with, the survey and its record are not regarded as complete, and the lands are still to be classed as unsurveyed. In other words, to justify the application of the term "surveyed" to a body of public land, something is required beyond the completion of the field work—namely, approval by the authorized officials of the federal government.[65]

C. B. HUMPHREY,[66] ESQ.—It is well that, from time to time, there appear, in the technical publications that reach the land surveyor, papers dealing with the problems of the surveyor in establishing and re-establishing boundary lines, and to remind him that, although the true lines of ownership are matters for a court, he may report the lines to the best of his knowledge.

Professor Holt's paper dealing with this subject is timely, when communities in the United States, with Federal Aid, are establishing coordinate systems to which may be referred all public and private surveys. His remarks upon the duties and limitations of a surveyor are most instructive, especially to young surveyors who, at times, seem to overlook the fact that most of their problems, pertaining to the interpretation of a boundary line, already have been determined by a court and the data acquired by a little research work.

The writer recalls reading "The Judicial Functions of Surveyors," by Mr. Justice Cooley of the Michigan Supreme Court and joins with Professor Holt in recommending that it be read by all interested in survey work. It appeared as "Appendix A" in "Theory and Practice of Surveying"[67] in 1892 and the writer, in his official duties, often quotes parts of this paper.

With reference to the establishment of a disputed boundary line by parol evidence or by agreement of interested parties, the surveyor may perform his functions as a surveyor by making a survey, setting bounds and preparing a plan for recording. As Professor Holt states, however, it may not be a judicial determination (which is a matter for a court) but it may be adjusted by direct grants between the respective owners.

---

[65] See U. S. Supreme Court decision in the case of Cox vs. Hart, 260 U. S. 427.

[66] Chf. Engr., Massachusetts Land Court, Boston, Mass.

[67] "Theory and Practice of Surveying," by J. B. Johnson, John Wiley & Sons, New York, N. Y., 1892.

In a Massachusetts case[68] that was an appeal from a Land Court decision, there was evidence that the disputed line had been fixed by a parol agreement by predecessors in title and the court ruled that although parties could agree orally, no title would pass by force of such agreement unless followed by occupation.

In proceedings in the Massachusetts Land Court there are many cases in which, after all the evidence is presented, disputed boundary lines are settled by written agreement or stipulation between the parties. The line thus agreed upon becomes a part of the final decree of the court confirming the title to the land and fixing all boundary lines.

The author has carefully emphasized that the determination of a disputed boundary line by either of the foregoing methods does not necessarily mean that it is the exact location as laid down by the original surveyor and shown on some recorded plat referred to, and from which one could, with safety, measure to reproduce all other lines.

In a Massachusetts case[69] the court held that the decision in a previous case whereby the line of a street was determined, although subsequently it was found that it was not determined in accordance with the plan from which the petitioners obtained title, did not prevent the petitioner in an adjacent case from insisting upon having the line of the street located in its proper position where it bounded upon his land.

To whom belong the field notes for a private survey? The writer contends that they belong to the professional surveyor, but that the surveyor should deliver to his client a plan and report that would be of value to a subsequent owner, and that he should show what an expert surveyor would call proper engineering data, and not a plat with plotting lines drawn to scale with distances only.

He should further recommend, as Professor Holt has so well stated, that if no monuments exist, sufficient monuments should be set to perpetuate and mark the lines surveyed and established. It is not always the fault of the surveyor that monuments are not set, but due to a short-sighted policy on the part of his client, which, in many cases, is the cause of the plan and survey being practically worthless when retraced after many years.

The author has presented an unusual paper, with helpful references to court cases, and it is hoped that it will be read by all those engaged in surveying practise. The writer also wishes to call attention to the coordinate systems now established by many states, a part of the expense of which is being borne by the federal government. The use of these systems by the engineering departments of various political subdivisions will enable more points to be established and should to a certain extent eliminate the duplication of survey work.

Many years have passed since G. Washington, Surveyor, placed the "corner stone" for the plantation under the Natural Bridge in Virginia and wrote his initials on the side of the cliff. The poplar trees, black oaks, white oaks and hickory corners mentioned in the "King's Grant" have long disappeared. Directions are no longer given in degrees only and distances in rods. The present-day surveyor, with modern instruments, must regard such common sources of errors as plumbing, alinement, temperature, wind, etc., and must think in terms of coordinates when locating a point on the earth's surface. He must also have in mind the standard used by previous engineers in laying down the Geodetic Control Stations if he is to agree with subdivisions between control lines. With these precautions, and coordinate values of record on recorded plats, there should be fewer disputes in the future as to the location of boundary lines.

[68] Crawford vs. Roloson, 256 Mass. 331.

[69] Pollard vs. Burchard, 199 Mass. 376.

D. D. HAINES,[70] ASSOC. M. AM. SOC. C. E.—In his "Introduction" Professor Holt makes a very good point when he states that a surveyor "must be ably advised on any given point concerning the law in the jurisdiction in which he is concerned." The mere fact that the law of one state provides that certain procedures must be followed in that state under certain conditions does not necessarily mean that the same procedure should be followed in another state. Statements of good law in one state must never be made to apply in another. A certain amount of local research on the subject must always be made. In laws relating to boundaries each state is an entity unto itself.

It is a well-known fact that not all states require that a surveyor be licensed, or registered, before he can do boundary surveying. However, if a surveyor is registered in a particular state, it is assumed that he is a "qualified" land surveyor; such qualification means that the surveyor has at least the minimum ability to exercise the necessary "ordinary prudence." Students invariably ask, "What is ordinary prudence?" This is a very natural question and one that defies a definite answer. Professor Holt has given the basis for the answer to such a question. Records must be pursued, boundaries examined, occupancy determined, and any other information carefully weighed; and furthermore the surveyor must tell his client just what the facts are as he sees them. The responsibility of a surveyor to his client is the same whether he is a registered or an unregistered practitioner. Should a surveyor fail to exercise "ordinary prudence," it is well known that he can be held liable for damages. To eliminate errors and secure the necessary precision in boundary surveying is not peculiar to that branch of surveying, nor to surveying in general, but to engineering as a whole. Professor Holt mentions the custom of giving a "certificate of accuracy" as a usual way of emphasizing accuracy. The writer would like to have Professor Holt enlarge on this subject.

The writer is frequently asked by students if a surveyor is actually a trespasser. The reply always has been that he is unless he has permission, or is exercising an official duty, and even then the surveyor is liable for actual damages as well as for any unnecessary damage he does. The author has made this point very clear. In the majority of cases, a surveyor can secure the permission of the owner to enter upon his land merely by explaining the need for such entry and promising to exercise due care. The surveyor should always keep in mind that he cannot force his way on to private property unless he has official authority, or unless a state statute definitely provides for such entry, and that in the majority of cases it is far better not to use authority unless absolutely necessary.

---

[70] Asst. Prof. of Civ. Eng., Univ. of Kansas, Lawrence, Kans.

It is well that this paper states that any survey will "hold" and become a "legal" survey when: (1) The results are accepted by those affected; or (2) the court rules that the survey properly settles the problem. Therefore, private surveyors and official surveyors have equal authority to "establish boundaries." Not enough laymen understand this fact.

Boundary disputes can be settled without court action. The realization of this fact is frequently startling to the young engineer or surveyor. Agreement may be reached between adjacent landowners when not in the presence of a surveyor, but since a surveyor is generally a part of such discussions he frequently can serve as an arbitrator. The surveyor is a better arbitrator if he understands the law thoroughly and if he has collected and weighed all the facts. Any award he makes will be considered valid, and any boundary fixed by agreement remains fixed regardless of mistakes of judgment or measurements. Although agreements to fix boundaries need not be in writing, it is better practice to make them of permanent record. One point cannot be overemphasized with respect to boundaries established by agreement and that is that the correct boundary line still has its place and importance, in that it (and not the agreed line) must be used as a starting point in the location of other lines and monuments.

The writer would like to have Professor Holt enlarge on the statement: "Such an agreement to fix a boundary line is void if the owners know or if one of them knows that the agreed line is not the true line" (see heading "Arbitration").

Professor Holt is quite right when he states that attorneys of general practice are not always entirely familiar with matters of boundaries. In fact, he could go further than that and state that they are seldom more than moderately familiar with such matters. Along this same line it should be noted that surveyors should not hesitate to consult lawyers as to the correct procedure to follow under certain circumstances. There must be a certain amount of "give-and-take" among the two professions to solve problems to their mutual advantage.

The discussion on the admissibility of plats and field notes is very interesting. The author has given a good bibliography for reference. It seems that field notes and plats from any source, so long as they are properly identified and authenticated, may, under the usual circumstance, be admitted as testimony.

The writer is glad that Professor Holt has seen fit to express his opinion to the effect that the most useful form in which a survey can be submitted to a client is a plat, thus leaving the survey notes in their original form with the original surveyor. Of course, the plat must be adequate and must give all the final data pertinent to the survey that the surveyor's client requested. The author's point (see heading "Surveyor's Report to His Client") that "graphical descriptions are often not only much more convenient than verbal ones, but much less likely to be misunderstood," is a good one and should cause more and more plats to be made and appended to legal description.

The entire paper is very interesting and worth while. Although most of the points discussed are problems that have been present for some time, they are constantly recurring, and are of sufficient importance to make it worth while to have them so ably reviewed.

COST OF PUBLIC SERVICES IN RESIDENTIAL AREAS

By F. Dodd McHugh,[1] Esq.

With Discussion by Messrs. Donald M. Baker, Howard Whipple Green, T. T. McCrosky, and F. Dodd McHugh.

The Problem

Material available, although not conclusive, shows that the United States is faced with a slowing up in the rate of growth. The greatest intensity of this change is felt in cities. During the decade 1910–1920 the population of New York, N. Y., increased 17.8% and that of the nation 14.9%. The increase was 23.3% for the city and 6.1% for the nation during the period 1920–1930. The U. S. Census Bureau reports an increase (in 1940) of only 6.5% for New York City and an increase of 7% for the continental United States since 1930.

Modern trends reveal a shifting of people from the older sections of the city to newer residential developments; but the older sections are only partly vacated and are rarely reoccupied by an influx of people or by new commercial activities. The preliminary report of the Census Bureau shows that Manhattan's population remained practically unchanged between 1930 and 1940, whereas the population of the four other boroughs of New York City increased from 4% to 20%. It now appears that, since the 1934 Real Property Inventory of New York City, some of the older sections of Manhattan have continued to lose population. The new developments in the northern part of the borough have apparently attracted a sufficient number of residents to offset the loss in older sections. The exact extent of this population shift cannot be determined until detailed information by census tracts for 1940 has been analyzed.

In 1934 the Real Property Inventory revealed that about 12% of all dwelling units in New York City were vacant, but that about 5% of Manhattan's dwellings were unoccupied. This inventory also shows that only four fifths of the dwelling units were occupied in the older apartment sections

---

Note.—Published in June, 1941, *Proceedings*.

[1] Director of Planning, Dept. of City Planning, New York, N. Y.

of Manhattan covered by this study. The Census Bureau's tentative report shows that 7.6% of all dwelling units were vacant in New York City as of April, 1940, and that about 11% were unoccupied in Manhattan. The census shows a gain in the occupancy ratio for the entire city as compared with 1934, but a decline for Manhattan. The meager data now at hand do not suggest that the older apartment districts of this borough have made any considerable gains in population subsequent to 1934. In fact, the preliminary census figures along with building permit, foreclosure, tax delinquent, and rental reports indicate that since 1934 the occupancy of dwellings in the older districts of Manhattan has probably not improved in relation to the city-wide occupancy ratio. Lacking any definite information to the contrary, it may be expected, therefore, that people are still leaving these older apartment districts to live in newer developments.

Why do people move from the older sections of cities? One explanation, given by Clarence A. Perry,[3] is applicable to practically all of the residential sections of New York City and other cities:

> "A prominent New York real estate man recently expressed the opinion that the 'normal life expectancy' of an ordinary dwelling was two or three times that of its neighborhood. In other words, the quality or desirability of a particular district tends to decline long before its component houses begin to wear out. Even so, this observation acquires a general significance only if it is discovered that the neighborhood deterioration affects the value of its individual houses. When the owner of a dwelling finds he can keep it occupied only by progressively lowering its rent, then its actual value is declining and the matter is of importance to the public, since that property is no longer able to bear its original share of the tax burden.
>
> "If this view is correct then the unsatisfactory conditions that lead families to give up their domiciles and move to new quarters become of private and public concern. If the dissatisfaction has arisen from something in the environment, it should be of special interest to the community because the matter is then beyond the power of the individual to correct and must receive attention from the public. That neighborhood conditions do cause people to move is a common view, but there is no unanimity as to just what these conditions are."

When old sections lose population, public services in these sections must be maintained and are usually operated below actual capacity. Meanwhile, additional public services must be supplied to the newer residential developments that are drawing population from the older sections of the city.

A survey made for the (New York City) Department of City Planning shows that one third of the city's gross area was vacant and unimproved in 1938. The 1940 federal census reports that in most of the larger cities of the United States, as well as in New York City, the rate of growth is slowing down. It is apparent from these facts and other considerations that the city has more than enough land available to house its present residential population and commercial activities, as well as any increase to be reasonably expected in the future. This outlook does not evidence a positive need to continue the extension of the city's physical growth to outlying undeveloped sections. The present economic and social conditions found in New York City obviously exist in many other cities. The prevalence of such unstable conditions would seem to require careful re-examination of the urban structure with particular reference to the possibilities of revitalizing the older sections of American cities.

---

[3] "Housing for the Machine Age," by Clarence A. Perry, Russell Sage Foundation, New York, N. Y., 1939, p. 15.

Constitutional and statutory provisions usually limit the debt-incurring and real-estate taxing powers of municipalities to a fixed percentage of the assessed valuation of real estate. In general, assessed values are not rising, and the increase of urban government income from all sources, including real-estate taxes, has failed to keep pace with the growing demand for expansion of public services. Consequently the cities' financial capacity to meet changing urban conditions is threatened seriously.

Some of the conditions underlying this study are peculiar to New York City. To the extent that such factors as high density of buildings and population reflect New York characteristics, the findings are not directly applicable to other municipalities. It seems, however, that the methods employed may be useful in measuring the magnitude of a problem that is common to most American cities, and that any differences between one city and another as may be revealed by similar studies will be mainly a matter of degree.

PURPOSE OF STUDY

An attempt is made in this paper to examine the problem in terms of city expenditures for permanent improvements and public services in old and new residential areas. Two types of residential areas are investigated: (1) A specimen community that is typical of the centrally located, existing residential development; and (2) a newer type of "neighborhood unit" development that is applicable to the rebuilding of old sections or in developing outlying vacant areas.

Costs are estimated for the public services found in the specimen community that represents existing conditions and for replacing the obsolete part of existing public facilities in this old area. The study also explores the public costs involved in rebuilding the old area on a neighborhood unit pattern, and in an identical new development to house the same population on raw land.

The sums that the private developer must spend for land and construction and carrying charges are not considered. Extensive studies by Messrs. Thomas Adams, M. Am. Soc. C. E., and the late Robert Whitten,[3] and Clarence Perry,[4] the President's Conference on Home Building and House Ownership,[5] the National Resources Committee, and others,[6] have approached the problem from planning and housing viewpoints with particular reference to the charges borne by the individual home owner and tenant.

PROCEDURE

A study of this nature is necessarily developed from, and limited by, hypotheses that may not be accepted in their entirety. It is believed, however, that the principles underlying this study furnish a sound approach to a complex problem.

The procedures used in this study involve the selection of the types and geographic location of specimen residential communities; the determination of land uses and building bulk in a specimen community representing old sections, and the allocation of land uses and fixing of building bulk in the "neighborhood units" as the basis for estimating the population that can be accommodated in each type of specimen community; the determination of the character and extent of public services existing in old sections and the needs for public services required to serve the residents of neighborhood units; and estimating the costs to the city for permanent improvements and annual operating expenses in each community.

CHARACTER OF DEVELOPMENT

The several community studies undertaken by the Mayor's Committee on City Planning prior to 1938 supply the most recent information on the character of development existing in the fully developed, high-density apartment districts located in the old central parts of the city. It should be noted that these communities are predominantly residential districts. In addition to dwellings, they have parks, schools, churches, local business, and other community facilities that serve residential needs. There are, however, cemeteries and industries in some of these communities that are not considered desirable within residential districts.

Existing Multi-Family Areas.—The Mayor's Committee Studies designated as East Harlem, East Side, and Yorkville are typical of existing conditions in the older apartment districts of Manhattan. Of their aggregate land area, 35.55% is used for streets on the gridiron system; only 2.7% is not built upon; 3.6% is parks; about 38.5% is residential; and the remainder is made up of business, industry, public buildings, and private institutions (see Table 1).[7] About 95% of the population lives in apartments and more than 87% of the residential land is used for multi-family housing.

The population was reported as 678,446 by the 1934 Real Property Inventory, but the total available family quarters were only 79.6% occupied. With full occupancy of all family quarters, 851,900 persons could be accommodated in the housing existing in these communities in 1934. The land areas expressed as acres per 1,000 persons in Table 1 are based on this estimate of "population provided for in existing housing."

If all apartments were occupied, the 851,900 persons housed on the 1,254.4 residential acres would produce a density of 678 persons per net acre! Allowing 70% coverage of residential land and 242 sq ft of building area per person, apartments would average 5.3 stories in height to house this population. As a rough check on this value for average height, it is only necessary to inspect these communities. One finds that most of the buildings are old "walk-up" flats or brownstone houses converted into apartments. Relatively few "new law" multi-family buildings of more than six stories will be seen and most of them are found on main thoroughfares. In Yorkville, for example, such apartments are situated along the north-and-south avenues and the major east-and-west streets.

---

[7] Data from East Harlem, East Side, and Yorkville Community Studies of the Mayor's Committee on City Planning (1935).

TABLE 1.—"BUILT-UP EXPERIENCE" IN CENTRAL APARTMENT COMMUNITIES OF NEW YORK CITY

Land Use	Area		Percentage of:	
	In acres	In acres per 1,000 persons	Gross area	Developed area
Developed Area:				
(a) Net Usable—				
Residential	1,254.4	1.47	38.49	39.56
Business	276.8	0.32	8.50	8.73
Industry	149.8	0.17	4.60	4.72
Institutions	209.4	0.28	6.42	6.61
Parks and Playgrounds	119.9	0.14	3.67	3.78
Cemeteries	1.5	......	0.04	0.05
Total net area	2,011.8	2.36	61.72	63.45
(b) Streets in use	1,158.8	1.36	35.55	36.55
Total developed	3,170.6	3.72	97.27	100.00
Vacant land	89.1	0.10	2.73	......
Gross area	3,259.7	3.82	100.00	......

The 1934 Real Property Inventory shows that about 85% of the buildings in East Harlem were erected prior to 1900, and further, that about 14% of these structures are between twenty and thirty-five years old. More than one fifth of the residential buildings need major repairs and two thirds require minor repairs; only 9% are in first-class condition. The 1935 survey of the Mayor's Committee on City Planning discloses that (1) nearly 23% of the properties in East Harlem were tax delinquent, and (2) that of a total assessed valuation of $263,000,000, land accounted for $125,000,000 or 47% of the total.

New Residential Units.—The diverse and sporadic development of individual properties under built-up experience usually produces the situation reflected in the foregoing examination of existing multi-family areas.

It is believed that urban blight may be combated successfully through large-scale planning and development, both in older, central, deteriorated districts and in new outlying districts. If such large-scale developments are not to become obsolete faster than the individual buildings therein, they must be of a size sufficient to permit the establishment of a self-contained neighborhood that can create a desirable residential environment and can maintain this character by preventing the occurrence of conditions that have caused people to move away from existing residential communities, leaving vacant dwellings and partly used public improvements that must be duplicated elsewhere. These new neighborhoods must also offer the amenities for urban living that will enable them to compete successfully with the newer developments that attract people from older sections of the city to suburban districts.

The Neighborhood Unit.—It is not the purpose of this study to formulate means nor to evaluate procedures suggested by others to promote the development of the newer type of residential neighborhood. Mr. Perry has presented[8] possible approaches to the problems inherent in development of neighborhoods. The neighborhood unit concept, as presented by Mr. Perry, sets the pattern for self-contained communities, and was adopted with minor modifications as the basis for ascertaining the costs of public improvements and services in newer types of residential developments. "The neighborhood unit—a scheme for arrangement for the family-life community" consists of six principles:[8]

(1) *Size.*—A neighborhood unit should provide housing for that population for which one elementary school is ordinarily required, its actual area depending upon its population density.

(2) *Boundaries.*—The unit should be bounded on all sides by arterial streets, sufficiently wide to facilitate its by-passing, instead of penetration, by through traffic.

(3) *Open Spaces.*—A system of small parks and recreation spaces, planned to meet the needs of the particular neighborhood, should be provided.

(4) *Institution Sites.*—Sites for the school and other institutions having service spheres coinciding with the limits of the unit should be suitably grouped about a central point.

(5) *Local Shops.*—One or more shopping districts, adequate for the population to be served, should be laid out in the circumference of the unit, preferably at traffic junctions and adjacent to similar districts of adjoining neighborhoods.

(6) *Internal Street System.*—The unit should be provided with a special street system, each highway being proportioned to its probable traffic load, and the street net as a whole being designed to facilitate circulation within the unit and to discourage its use by through traffic.

In addition to the foregoing principles the neighborhood unit formula as used in this study implies that: (1) Building density should be limited to insure light and air to residents and to prevent unnecessary overcrowding of the land; (2) the unit should be fully developed in order to utilize land, buildings, and public services efficiently; and (3) public and private facilities should be adequate to meet the needs of the people living in such self-contained residential neighborhoods. These principles of the unit scheme can ordinarily be fully applied to new developments only. Consequently, the neighborhood unit principle may be limited to outlying unbuilt areas and to the rebuilding of centrally located deteriorated districts.

Types of Development Studied

This neighborhood unit formula seems to present a sound technique for the development of communities that will avoid the incipient blight and early deterioration experienced in existing residential sections. If this new type of development can establish and maintain a desirable environment for residential neighborhoods, stabilize development, and conserve values by helping to prevent unnecessary shifting of population, then the relative costs of public improvements in such neighborhoods are of considerable interest. This paper, therefore, undertakes to examine two types of development—(1) an area characteristic of existing development, and (2) a new neighborhood unit that could be used in rebuilding the old area or for a new development on vacant land.

---

[8] "Neighborhood and Community Planning," Regional Survey, Vol. VII, Regional Plan of New York and Its Environs, 1929.

Existing Area Selected for Study.—The character and extent of development in specimen Area *A*, Fig. 1, is determined by the "built-up experience" exhibited in the three multi-family communities surveyed by the Mayor's Committee on City Planning. (The locations shown in Fig. 1 are not intended to designate specific areas but merely to show the approximate locations.) Area *A* is a fully developed apartment district situated in the central city; it is typical of the "built-up experience" in existing multi-family areas that are developed on a gridiron street plan. Such areas are usually found in the older sections of most large cities.

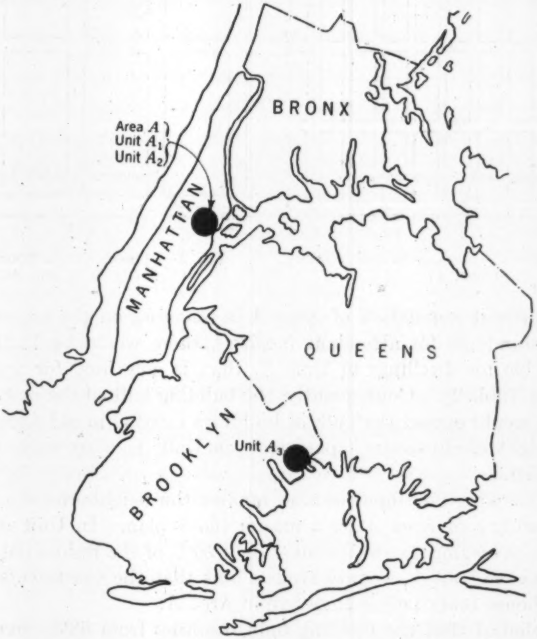

FIG. 1.—APPROXIMATE LOCATION OF THE 160-ACRE COMMUNITIES, NEW YORK, N. Y.

New Units Selected for Study.—Each of the neighborhood unit types of development selected for study is predicated upon the principles underlying the unit formula and upon the following minimum "standards":

Unit A_1.—This development represents an attempt to apply the neighborhood unit scheme in the rebuilding of Area A on a super block plan, which involves the conversion of the "normal" street system shown in Fig. 2 to the master block plan in Fig. 3. It provides sufficient new apartments to rehouse the present population of Area A, and the necessary private facilities and public services required to serve this population.

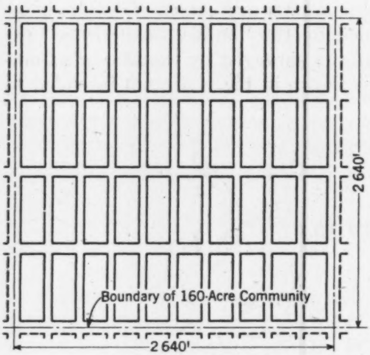

FIG. 2.—"NORMAL" GRIDIRON STREET SYSTEMS (AREA A)

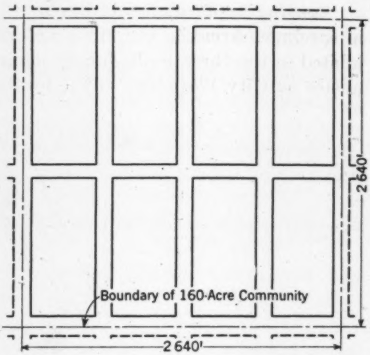

FIG. 3.—MASTER BLOCK STREET SYSTEMS (UNITS A_1 AND A_2)

If the present population of Area A is rehoused on the same site, under minimum standards for attendant facilities, there would be 15.11 acres less land available for dwellings in Unit A_1 than is now used for apartments in Area A (see Table 2). Consequently, the building bulk of the new apartments in Unit A_1 would exceed the bulk of buildings existing in old Area A. At an average height of six stories, apartments in Unit A_1 must cover 68% of the residential land.

Unit A_2.—This development also applies the neighborhood unit formula in the rebuilding of Area A on a master block plan. In Unit A_2, however, apartments averaging six stories cover only 50% of the residential land. The new buildings in Unit A_2 would have less bulk than the apartments and would, therefore, house fewer people than live in Area A.

It is believed that the building bulk resulting from 68% cover, six story apartments, which is required in Unit A_1 to rehouse the present population of Area A on the same site, would make that new unit an obsolete development. The apartments in Unit A_2, covering only 50% of the residential land and averaging six stories in height, provide more open space and permit a better layout which would probably be subject to a much lower rate of obsolescence than the bulkier buildings of Unit A_1.

Unit A_3.—Unit A_3 is a new apartment development on raw land; it is identical to Unit A_2 and houses the same population; but entirely new public facilities are needed in the undeveloped outlying section selected as a site for Unit A_3. This development is predicated on six-story buildings covering 50%

of the residential land. Such a building bulk is not desirable in outlying districts; nor should it be implied that this study so recommends. The purpose of this theoretical development, the same as the other units, is to afford a direct comparison of the results obtained.

Land Area of Speciman Communities.—The specimen area and units studied are considered predominantly residential in character with only such local business, recreational, and cultural facilities within their boundaries as are required for the convenient service of the persons housed in each community.

[a] Percentage of residential land covered by apartments. [b] Persons housed after allowing for vacancies.

In order to measure public services in the existing area and to ascertain needs in the new units that could be reduced to comparable terms, it was necessary to find a common denominator. Accordingly, each of the communities studied is a type or specimen development predicated on a square containing 160 acres, measured to the center line of boundary streets, in order to secure comparability in one respect—namely, land area. It should be noted that the area of 160 acres, developed with apartments of the character assumed in this study, would house more people than could be efficiently served by one elementary school. Under the foregoing principles of the neighborhood unit, such a development might be served by several elementary schools.

Location of Communities Studied.—There is no particular advantage, however, in examining an area of 160 acres within designated boundary streets. The value of the findings could be easily prejudiced by conditions peculiar to a specific location. It is true that a number of unit costs vary, as between the boroughs of New York City, due to differences in construction practices and in the extent to which certain city services are normally provided, but there is no significant variation within a borough. Approximate locations, within a well-defined section of a borough, furnish ample bases for determining the extent of public development existing in an area typical of that section and the costs of public facilities prevailing in the vicinity. The resulting cost estimates are more representative of average conditions for large sections of the city and, therefore, have broader implications.

Accordingly, Area A (see Fig. 1) is located within the East Harlem section of Manhattan; Units A_1 and A_2, the two schemes for rebuilding multi-family Area A, of course, are on the same site as Area A in East Harlem; and Unit A_3 is located on vacant land, adjacent to Jamaica Bay in Brooklyn, N. Y.

LAND USE, BUILDING DEVELOPMENT, AND POPULATION

The area of land used for various purposes and the bulk of buildings determine the number of persons that can be accommodated in these communities. The population of the specimen communities must be ascertained before the extent and cost of public facilities can be investigated.

Land Use.—Two major factors are involved in allocating the 160 acres of these typical communities to street, residence, institution, park, and business uses—namely, area and population. The land required for street purposes is determined by the street plan, and in the old area both vacant land and streets are based on the extent of existing development. The land area needed for residence, parks, institutions, and business, however, is dependent upon the number of persons to be housed in a given community; hence, the extent of these land uses is predicated upon the service requirements of the community's population.

The "Area" Factor.—As shown in Figs. 2 and 3, the communities studied are developed on the two types of street systems: (1) The "normal" gridiron street plan; and (2) a master block arrangement.

Gridiron Street Plan.—The usual gridiron street plan existing in New York City is not directly adaptable to a theoretical community of 160 acres, in the form of a square measuring one-half mile on a side. Minor adjustments in the occurrence of the wider streets and avenues in relation to the local streets of standard width are, however, satisfactory for the purposes of this study. The gridiron street system was standardized in a "normal" pattern to permit direct comparisons between communities (see Fig. 2). The amount of land in Area A that is allocated to the gridiron street plan on this "normal" pattern is based upon the built-up experience of existing multi-family areas (see Tables 1 and 2). The boundary streets of Area A average 100 ft in width, and the "normal" gridiron system requires nearly 57 acres, or about 35% of the 160-acre gross area. Each block measures 575 ft by 200 ft.

Master Block Plan.—The master block arrangement indicated by Fig. 3 is used for Unit A_1, Unit A_2, and Unit A_3. This development plan of "super" blocks is designed to limit "through" traffic to boundary and major thoroughfares. Boundary streets of the 160-acre tract are each 140 ft wide, including a local service road. Each master block (1,200 ft by 535 ft) is surrounded by a service roadway separated by a safety isle or planting strip from the wider through-traffic streets bounding the block. A single master block is equivalent to five ordinary blocks in the usual gridiron system, including the area devoted to four minor cross streets in the gridiron system but excluding the area needed for service roadways. The theoretical 160-acre community has eight such master blocks in two rows of four each. They are separated by three north-and-south streets, each 120 ft wide with service road, and by one east-and-west street, 100 ft wide, running through the center (see Fig. 4).

Master Block Street System

FIG. 4.—CONVERSION OF "NORMAL" GRIDIRON STREET SYSTEM OF AREA *A* TO MASTER BLOCK LAYOUT FOR UNITS A_1 AND A_2

This master block plan is applicable in the rebuilding of most of the old sections that are now developed on a "normal" gridiron street system and can be easily used for any neighborhood to be built on a vacant and relatively flat site. In this design, streets account for about 42 acres, or 26.3% of the 160-acre gross area.

"Population" Factors and Standards.—With the street pattern fixed, the next step in the determination of land use involved the allocation of the remaining acreage to the parks, institutions, business, and residential uses needed by the community's inhabitants.

Reference to Table 1 will recall that there are cemeteries and industries in the large communities surveyed by the Mayor's Committee on City Planning. Within these larger communities, however, there are many sections of 160 acres that do not contain either a cemetery or any significant industrial uses. For the purpose of this study, therefore, such uses are excluded from all of the communities.

Uses in Terms of Population.—The extent of public services and private facilities needed in the neighborhood units is necessarily determined by the total number of people that can be housed in each community. In the case of an "old" development, it is reasonable to express land use and service needs in terms of the population that could live in the area if all available dwellings were occupied. Otherwise, any measurement of adequacy is based on a population figure which fluctuates with the changing occupancy of dwellings, and a facility deemed adequate for 80% occupancy is found insufficient when 90% of the dwelling units are occupied. In this study, therefore, any land use or facility depending upon the population factor is predicated on 100% occupancy of available family quarters. Real Property Inventory reports show that few of the "old" residential districts are fully occupied, but the newer and more modern housing developments usually have a "waiting list" of families that desire to move in as soon as a vacancy occurs.

It is believed that some of the buildings have become entirely vacant since 1934 and are boarded up or demolished; but subsequent new construction and alterations have probably added some family quarters in the existing multi-family areas. However, there are no data available to indicate the exact number of family quarters now existing in Area *A*. Consequently, the conditions revealed by the 1934 Real Property Inventory are used to estimate the population resulting from 100% occupancy of family quarters in Area *A*.

Built-Up Experience in Area A.—The analysis of selected existing multi-family areas, surveyed by the Mayor's Committee on City Planning, reveals that there would be 678 persons per residential acre if all family quarters were occupied. In Area *A*, the 678 persons per net acre are housed in apartments averaging 5.3 stories in height and covering 70% of the residential land.

Full occupancy of the family quarters provided in Area *A* determines the total population and extent of land used for residence, parks, institutions, and local business. Table 2 shows the number of acres and the proportion of gross land area used for each major purpose as well as the population provided for under built-up experience in the 160-acre specimen community, Area *A*. The acres per 1,000 persons of park, institution, and local business found in Area *A* are given in Table 1.

"Minimum Standards" in Units.—The extent of land required for each major purpose in the neighborhood units is predicated on the unit formula and the minimum standards for parks, institutions, local business, and housing, as follows:

Park and Playground.—Standards believed feasible in New York City, which were developed by the Mayor's Committee on City Planning, call for a minimum of one acre of park and playground per 1,750 persons. This allows for a playground, a small quiet park, and active recreation areas but excludes large parks.

Institutions.—Schools, fire stations, libraries, and other public and private buildings of a local character, as well as churches, are included under "Institutions." Because of the varying spheres of influence of such services, some of which do not coincide with the 160-acre tract under consideration, the land allocated to institutions in each unit is based upon the average built-up experience of eleven residential communities studied by the Mayor's Committee on City Planning. This average is just more than one half of an acre per 1,000 persons, and is believed to be generally adequate.

Business.—Local business includes retail shops, garages, gas stations, laundries, cleaners, barbers, theaters, banks, amusements, local offices, and similar services that would be needed by the people of a self-contained residential community.

In this study the business standard is fixed at 50 ft per 100 people. With lots averaging 100 ft deep this is equivalent to one acre of business per 870 population in each neighborhood unit. Table 1 shows that about 0.3 acre per 1,000 people is used for commercial structures in the existing multi-family areas of the city. The remaining business frontage usually required to serve such communities is found on the ground floor of apartment buildings. Consequently, in Units A_1 and A_2 (the alternative schemes for rebuilding Area A), and in Unit A_3, it is assumed that one half of the required business frontage is on the ground floor of multi-family buildings and the remainder in commercial structures.

Residential Requirements.—In rebuilding Area A to rehouse the present population of 36,620 persons, provision is made in Unit A_1 for a normal vacancy of 5%. On this basis the new apartments must accommodate 38,550 persons. Allowing 242 sq ft of gross floor area per person, and buildings averaging six stories high, these apartments would cover approximately 68% of the net residential land. If land coverage is held to 50%, the buildings would average 8.15 stories in height. In either case there would be 731 persons per net residential acre compared with a potential density of 678 in Area A. This greater density in Unit A_1 results from the relatively larger land areas that are devoted to park, institutional, and business purposes under minimum standards, which reduce the area of land available for residence (compare Area A and Unit A_1 in Table 2). Although these other facilities may be considered adequate, the building bulk of apartments in Unit A_1 is believed to exceed a reasonable standard in overcrowding the land and is therefore considered obsolete.

It is assumed that the housing bulk resulting from 50% land coverage and six-story apartment buildings is the maximum development desirable under reasonable standards. At 242 sq ft of gross floor area per person, these apartments would accommodate 540 people on each residential acre. When properly designed, it is believed that such a development could offer sufficient amenities to maintain a desirable residential character despite the high density. Accordingly, this average building bulk is the housing "standard" in rebuilt Unit A_2 and in new Unit A_3.

Application of Factors and Standards.—Using the aforementioned factors and "standards," the requirements of the population for residence, park, institution, and business were determined for each of the neighborhood units. The resulting population and the land area allocated to these major uses are given in Table 2. Inasmuch as the neighborhood units are fully developed, there is no vacant land.

PUBLIC IMPROVEMENTS AND SERVICES

This investigation attempts to ascertain the nature and extent of public improvements and services now provided in Area *A*. The land uses and degree of development in Area *A* are derived from the built-up experience of the larger communities of which this theoretical 160-acre area is a representative sample. Likewise, the character and extent of public improvements and services in Area *A* are determined from the built-up experience in the larger residential community of East Harlem. The average conditions revealed by public records to exist in East Harlem, when applied to Area *A*, indicate the public facilities now serving this theoretical 160-acre community.

The public services required to serve the neighborhood units adequately are determined on the basis of "minimum service standards," which are discussed herein. Practically all of the public facilities required to serve Unit A_3, which is situated on vacant land, must be entirely new improvements.

In the rebuilding of Area *A* on a master block plan, it is also necessary for the city to provide the adequate and up-to-date facilities needed under "minimum service standards" by the population rehoused in each of the alternative neighborhood schemes, Units A_1 and A_2. Therefore, it is assumed that: (1) Any public facility existing in Area *A* that is not adequate as measured by minimum service standards must be augmented in Units A_1 and A_2 to the full extent of the indicated deficiency; and (2) all existing public services in Area *A* are utilized in so far as needed, but those retained must be replaced in Units A_1 and A_2 to the full extent of the indicated obsolescence.

Improvements and Services Studied.—Only those permanent improvements and facilities supplied by the city that may be directly charged to a local community on the basis of services provided are included in this study. The needs for water supply reservoirs, courts, jails, hospitals, museum buildings, and other general services are not determined by the type of residential development, and they are influenced only indirectly by the geographic location of residential communities. In comparison with local neighborhood facilities, such improvements are city-wide services for which the needs are determined by the entire population and area of the city or a borough. In this study the public services discussed are considered essential to the proper functioning of self-contained residential communities.

Street Utilities.—Sidewalks, curbs, street paving, sewers, water mains, and street lighting are termed "street utilities" in this study. The installation of these utilities in New York City depends almost entirely upon the type of street plan and the various construction practices in each borough of the city rather than upon the number of people to be served.

The borough standards, quantities, and unit costs of street utilities are given in the Appendix. The "minimum service standards" for street utilities in the neighborhood units coincide with current practice in the boroughs, but the quantities needed, or course, are determined by the master block layout.

Population Facilities.—Population facilities include parks and playgrounds, elementary and high schools, branch libraries, district health buildings, fire and police stations, sanitation services, sewage and refuse disposal, and rapid transit. With the exception of rapid transit, which is located in public streets, population facilities are built upon a part of the "developed area" that is classified as "Institutions" in Tables 1 and 2.

The extent to which these public improvements and services are provided in Area *A* and are needed in the neighborhood units is determined by the population to be served. This does not imply that all such services existing in Area *A* are adequate to meet the needs of modern urban living, but rather that the basic requirements for these facilities are not dependent upon the land or "area factor" alone. For example, schools are provided to accommodate a given number of children, and the "area served" depends upon the size of the school and the density of population in the surrounding development. Other parallels can be drawn but the relationship between population and schools illustrates the general nature of "population facilities."

Practically all of these population facilities have been provided in the larger residential communities surveyed by the Mayor's Committee on City Planning. In general, small parks, schools, and sanitation services are entirely local in character, but the other population facilities may have sufficient capacity to take care of a greater number of people than are accommodated in a typical 160-acre community. Existing facilities with an "area of service" greater than 160 acres may not be located within the boundaries of a 160-acre district, and the extent of service available to each community must be based, therefore, on borough or city-wide measurements in relation to the needs of the population of each of the theoretical communities.

The public improvements and services in the neighborhood units that are dependent upon the population factor are identical to the population facilities supplied to Area *A*, and the same procedures are used to determine the extent of each service needed. The "minimum service standards" for parks and playgrounds, elementary schools, libraries, refuse disposal, and rapid transit service in the neighborhood units differ from current borough practices. City standards and departmental programs for the remaining population facilities are considered adequate for the units. The methods of determining needs, and the "standards" and charges against each community for population facilities, are outlined in the Appendix.

OBSOLESCENCE IN AREA *A*

In rebuilding Area *A* under the "standards" adopted for this study, it would be necessary to expand existing public services that are inadequate and to replace any depreciated facility to the full extent of indicated obsolescence.

Street Utilities.—Fig. 4 suggests the extent of alteration and rearrangement of "street utilities" involved in the change from the normal gridiron street system of Area *A* to the master block plan of Units A_1 and A_2. The changes, quantities, and costs involved are given in the Appendix.

Population Facilities.—Many of the existing population facilities serving Area *A* must be replaced in whole or in part when this old district is rebuilt on the master block plan of Units A_1 and A_2. The obsolescence of population facilities serving Area *A* generally is predicated on the present age and useful life of these improvements.

The present age of facilities is obtained from public records, with the exception of libraries, fire stations, police precincts, and sanitation garages and section houses. It was assumed that the age of these facilities is equal to the average age of existing school buildings in East Harlem. The first school in this section, still standing in 1941, was built in 1867, but the average age of all schools in East Harlem is forty-three years. It seems reasonable to suppose that the average age of the aforementioned facilities in East Harlem will approximate the average age of schools.

The useful life of most population facilities is derived from the replacement experience of the appropriate public agencies. Whenever a facility reaches the limit of its useful life, replacement is assumed necessary for the satisfactory continuance of such service. The Appendix contains detailed information on the present obsolescence of public services in Area *A*.

IMPROVEMENT COSTS AND ANNUAL EXPENSES

The reported costs of existing improvements in old Area *A* are used when available. In other instances the estimates are derived from current contract prices reported by city agencies. The cost estimates for improvements in neighborhood units are based upon current practice and contract costs in the appropriate borough, or upon the estimated costs of proposed improvements. Land acquisition is estimated at 1.3 times the average assessed value per acre in each community, but all street land is assumed to be dedicated without cost to the city. The cost estimates for each kind of improvement or service are summarized in Table 3(*a*) by community.

The unit costs used in the estimates of annual expenses are derived from the most recent information available from the operating agencies. The per capita expenses, where used in this investigation, are generally obtained from reported total annual expense and the estimated population actually living in the city. The "actual" population living in each community, rather than the "demand" or total population that could be accommodated with 100% occupancy of dwelling units, is used, therefore, in determining annual expenses that are based on per capita costs.

The estimates of annual expenses indicate the expenditures of the city for operation and maintenance of public services provided in each community. No attempt is made to set up a "balance sheet" of annual expenses and of city revenue derived from a community. The estimates do not in any sense represent the amounts of taxes levied or collected in each community. Annual expenses in any of these residential areas may exceed the taxes paid to the city by the particular community, but the expenses must be met from general city revenues in any event. The estimated yearly expenses charged to each community are summarized in Table 3(*b*), and the procedures in this work are outlined in the Appendix.

Meaning of Estimates.—The estimated costs of permanent improvements represent the present investment of the city in the public facilities now found in Area *A* without any allowance for depreciation or for replacement of the original improvements. The estimates of annual expenses represent the costs to the city for operation and maintenance of existing public services, some at less than capacity because of the relatively low occupancy ratio in dwellings of Area *A*.

TABLE 3.—ESTIMATED TOTAL COSTS TO THE CITY

No.	Description	Area *A*	Unit A_1	Unit A_2	Unit A_3

32	Debt service on rapid transit	80,900	160,400	119,200	346,000
33	Total annual expenses	$ 1,609,976	$1,522,348	$1,305,886	$ 1,357,106

The costs of public improvements in the neighborhood Unit A_3 represent the investment that the city must make to provide new public services that are adequate under minimum service standards. The estimated costs of permanent improvements in the rebuilt communities, Units A_1 and A_2, represent the city expenditures necessary to make existing deficient services adequate and to replace the obsolete part of the present plant that is retained in rebuilding the old apartment Area *A*. The estimates of annual expenses indicate the costs to the city for operation and maintenance of public services in the neighborhood units with 95% of the available housing occupied.

Total and Per Capita Costs.—Rapid transit is not the same kind of local improvement as elementary schools and similar neighborhood facilities. However, transit has exerted a tremendous influence upon the direction and extent of residential development. Since 1900 about 85% of New York's population has lived within one-half mile of rapid transit lines. Urban life depends upon mobility of people as well as goods. Rapid transit, therefore, is considered essential to the life of residential communities in New York City. Rather than permit the transit factor to complicate these findings, the estimated costs will be examined, first with transit charges and second excluding transit charges.

The findings will be considered on the basis of "costs per person housed" in each area. The "costs per person housed" are based upon the actual population living in each area after allowing for vacancies.

With Rapid Transit Charges.—Total improvement costs in new Unit A_3 are 1.15 times the costs in old Area A, and the costs per person housed in Unit A_3 are 1.33 times the per capita costs in Area A (see Table 4(*a*)).

A_2	3,781,510	119.66	1,305,886	41.32	2,998,110	94.87	1,186,686	37.55
A_3	12,740,534	403.18	1,357,106	42.94	5,659,934	179.11	1,011,106	31.99

Per capita improvement costs for new Unit A_3 are much larger than the costs involved in rebuilding old Area A; costs per person housed in Unit A_3 are 3.3 times the cost in rebuilt Unit A_2 and 2.4 times the per capita costs in rebuilt Unit A_1. This is significant because the rebuilt Units A_1 and A_2 provide additional services to meet present deficiencies of old Area A, and because the deteriorated parts of existing facilities are replaced to the full extent of the indicated obsolescence. It is also interesting to note that the city needs to spend less than $120 per person to house a population of 31,600 in Unit A_2, compared to $163 per person to house 36,620 people in Unit A_1.

Annual expenses per person housed do not vary as much between the several communities as improvement costs. The range is from $41.32 in Unit A_2 to nearly $44 in Area A. The higher total and per capita expenses in Area A suggest that public services in deteriorated old sections are not utilized efficiently. The costs per person housed in new Unit A_3 are $42.94, as against $43.96 in Area A and $41.57 in rebuilt Unit A_1 (see Table 4(*a*)).

Excluding Transit Charges.—If rapid transit should become an entirely self-sustaining service, the costs to the city for improvements in residential developments would be reduced accordingly. The exclusion of transit charges reduces the remaining improvement costs in new Unit A_3 to about 60% of those in old Area A; but the costs in Unit A_3 are 1.3 times the costs in rebuilt Unit A_1 and nearly 1.9 times the costs for improvements in Unit A_2 (see Table 4(*b*)).

In terms of persons housed, the costs are lower in the rebuilt units than in the new development. In new Unit A_3 the improvement costs per person housed are 1.5 times the costs in rebuilt Unit A_1, and about 1.9 times more per person than need be spent in rehousing an equivalent population in rebuilt Unit A_2.

Annual operating expenses are lower in new Unit A_3 than in other communities when transit charges are deducted. Per capita service expenses are generally higher in Manhattan, and in many instances a larger measure of service is provided than in Brooklyn. The expenses per person housed in new Unit A_3 are about 75% of the expenses in Area A, and approximately 83% of expenses in Units A_1 and A_2.

Rehabilitation Versus Decentralization

The surprisingly low per capita cost for the rebuilt Unit A_2 is particularly interesting. The conditions existing in Area A are indicative of the deficiencies of older residential districts in central parts of the city. The average age of this development exceeds forty years; some of the public facilities and private structures are more than seventy years old.

Certain public services are inadequate as measured by the standards adopted for this study, and many existing public improvements are nearing a point of deterioration that will shortly necessitate their replacement. A variety of circumstances have contributed to the high vacancy in apartments, among others being: (1) The heavy vehicular traffic passing through the district on local streets; (2) an influx of commercial and industrial activities into residential blocks; (3) too great a density of buildings and people on the land; and (4) a hesitancy of owners to modernize old housing. Private owners do not wish to increase their investment in old buildings because of the uncertain outlook for individual properties and the hope of putting the land to a more intensive use. This hope has not materialized, but modernization is difficult because many properties have not been amortized over the years of productive use. These and other circumstances make Area A an unstable district, and the lack of bold correctives further contributes to this unhealthy condition. It is only natural that people should move from districts like Area A whenever they can afford to locate in newer, outlying sections that offer a more desirable residential environment.

When population shifts from older districts to newer developments, the city must provide additional street utilities and population facilities in the new sections to meet the resulting demands. There are enough people left in the older districts, however, to require the maintenance of public services. Consequently, the city is in reality forced to duplicate existing facilities in the newer developments and at the same time to operate the old plant below capacity.

The older residential districts cannot be abandoned entirely and left to stagnate; nor are the people willing to remain in these undesirable neighborhoods so long as modern private developments and cheap transportation enable them to live more pleasantly in outlying communities. What can be done to remedy this apparent impasse? Under present tax structures the city cannot continue this inefficient and expensive process unless it is to face bankruptcy or to experience a far greater population growth than the more optimistic prognosticators now foresee.

This investigation suggests that, in so far as city expenditures are concerned, it would be economical and desirable to rehabilitate deteriorated residential districts completely on the neighborhood unit scheme. A brief examination of the current obsolescence of public services will reveal the extent of investments to be salvaged in this process and the cost of rehabilitation as against decentralization.

Public Facilities in Area A.—Table 3 shows that the costs to the city, for modernization of existing public facilities in Area A on the master block scheme of the neighborhood Unit A_1, amount to about $6,000,000, or $163 per person housed. This value does not indicate the exact obsolescence of existing public facilities because of the changes in street utilities necessitated by the conversion of the present gridiron street system of Area A into the master block plan. The extension of population facilities required by minimum service standards also calls for a greater expenditure than is necessary merely to replace the obsolete part of the existing plant. A calculation of the costs of replacing obsolete public facilities in Area A, without changing the present gridiron street plan, shows that a total outlay of about $4,900,000 would be needed. Of this total, replacing obsolete street utilities would require $850,000 and merely replacing obsolete population facilities would involve expenditures of more than $4,000,000. The replacing of obsolete facilities without altering the gridiron street plan of Area A, or supplying adequate parks, is herein termed operation "Re-Area A."

Assuming that the $11,065,446 cost to the city for improvements now existing in Area A is the original public investment, the estimated expense of replacing deteriorated parts is 44.3% of this original cost. In other words, it appears that public facilities in Area A are already 44% obsolete and must be replaced shortly in order to maintain city services for the 36,620 persons living in this community. This of course excludes replacing such new improvements as the sewage disposal plant and a local health building.

Replacing Facilities with Adequate Parks.—When the city does replace obsolete facilities in old Area A, it would be preferable to provide the additional park acreage required under minimum service standards to serve the present population. The Appendix shows that the transformation of the gridiron street system into the master block plan makes it possible to obtain new park acreage by utilizing the land available from interior streets, which are discontinued. In the case of Unit A_1, the required total park acreage exceeds the sum of existing park area plus leftover street area by only 2.5 acres. On this basis the city needs to purchase 2.5 acres of additional land to meet the park requirements of Unit A_1.

By rehabilitating public improvements in old Area A without changing the existing gridiron street system to the master block plan, the city would not be able to discontinue any local streets. As a result, it would be necessary to purchase more than 17 acres of land which, with the 4.8 acres now in parks, would provide the 22 acres of parks and playgrounds needed to serve, adequately, the present population of old Area *A*. This operation can be designated as "New Area *A*."

With land acquisition at 1.3 times the average assessed value and development costs at $7,000 per acre, parks cost more than $6,400,000 in this rehabilitation operation for New Area *A* under minimum standards. The replacement of obsolete street utilities and population facilities, other than parks, requires the same expenditure as in Re-Area *A*—namely, about $4,900,000. The total cost of up-to-date public facilities in New Area *A* on the old gridiron street plan exceeds $11,300,000, or $308 per person housed.

Cost Ratios Per Person.—It is significant to find that the rebuilt Unit A_2 is less costly in respect to public services than "Re-Area *A*," "New Area *A*," or the new Unit A_3. Because of this finding the per person cost ratios in Table 5 are based on the cost in Unit A_2 as 100.

TABLE 5.—CITY EXPENDITURES PER PERSON

(With Transit Charges)

Community	IMPROVEMENT COSTS		ANNUAL EXPENSES	
	Per person	Ratio	Per person	Ratio
Old Area *A*[a]	$ 302	252	$43.96	106
Re-Area *A*[a]	134	112	42.15	102
New Area *A*[a]	308	258	42.30	102
Unit A_1[a]	163	136	41.57	101
Unit A_2[b]	119	100	41.32	100
Unit A_3[b]	403	337	42.94	104

[a] Population housed is 36,620 persons.
[b] Population housed is 31,600 persons.

The replacement of obsolete public facilities, without altering the gridiron street plan of Area *A*, would cost the city 12% more with present park acreage and nearly 2.6 times more with adequate park area than the rebuilding of old Area *A* on the master block scheme of Unit A_2. The rebuilding of Area *A* on the master block plan of Unit A_1 would cost only slightly more than merely replacing obsolete facilities for Re-Area *A*, but less than for New Area *A*.

The replacing of obsolete facilities for Re-Area *A* and New Area *A* would not, however, produce the social and economic results believed possible with the neighborhood unit communities on a master block plan. Such replacement of public facilities would tend to "freeze" the present character of private development on the unsatisfactory gridiron street plan, and to postpone the necessarily bold public and private corrective measures for at least another fifty or seventy-five years. By that time it is probable that the social and economic conditions of this community will become quite chaotic, unless present trends could somehow be arrested.

The advantages of the neighborhood unit schemes, having already been enumerated, will not be repeated. It is surprising to find, however, that such sound types of redevelopment as the neighborhood Units A_1 and A_2 also have cost advantages over the replacement of obsolete facilities, both for permanent improvements and annual operation. The entirely new neighborhood Unit A_3 is much more expensive than the several types of rehabilitated communities. When one recalls that, to a considerable extent, the public facilities in this new unit would duplicate city services now provided in other sections of the city that are already built up, the apparently favorable ratio for operation in Unit A_3 is reduced accordingly.

These findings are not entirely conclusive, but they indicate that large-scale rehabilitation of old central apartment districts is economically feasible and preferable to new developments in outlying sections in so far as city expenditures are concerned. When one considers that all residents pay local taxes, which are obviously increased through duplication of city services, the case of rehabilitation versus decentralization becomes a question of public concern. It would seem, therefore, that essential studies of the private costs involved, and of the procedures to be used in large-scale rehabilitation of entire neighborhoods, should be undertaken immediately under a joint private and public sponsorship.

ACKNOWLEDGMENTS

The original investigations, from which this paper is drawn, were made during 1939 for the Department of City Planning of the City of New York to ascertain the relative costs of public services in various types of residential developments. Commissioner R. G. Tugwell (who heads the Department and is Chairman of the City Planning Commission) has been kind enough to release the material for this paper prior to publication of the full report on the original study.

APPENDIX

The extent of public services existing in Area *A*, the standards used to determine the needs for improvements in the neighborhood units, the obsolescence of facilities now provided in Area *A*, and the cost estimates are outlined herein.

The reported costs of existing improvements in old Area *A* are used when available. In other instances the estimates are derived from current contract prices reported by city agencies. The cost estimates for improvements in neighborhood units are based upon current practice and contract costs in the appropriate borough, or upon the estimated costs of proposed improvements. Land acquisition is estimated at 1.3 times the average assessed value per acre in each community, but all street land is assumed to be dedicated without cost to the city.

Street Utilities.—The quality of street utilities is fixed by construction standards in the various boroughs, and the quantity is determined by the street plan and character of development. The quantities and unit costs (based on recently reported contract prices) are summarized in Table 6.

Sidewalks and Curbs (Item No. 1, Table 6).—Sidewalk standards in Manhattan call for 7 in. of cinders, 4 in. of concrete, and 1 in. of cement with steel-faced concrete curbs. The Brooklyn standard is 6 in. of cinders and 5 in. of concrete. Straight curbs are concrete in Brooklyn, but granite is used for corners and 3 ft beyond the corner curve.

Street Paving (Item No. 2, Table 6).—One half the cost of paving the through traffic roadway of boundary streets is charged to each community; but the service roadway adjacent to boundary streets in the master block plan, as well as other paving within the community, is charged in full to the neighborhood units.

TABLE 6.—STREET UTILITIES

No.	Item	AREA A		UNITS A_1 AND A_2		UNIT A_3

[a] Curbs for safety islands in master block layout. [b] 70% of length shown obsolete and replaced.
[c] 50% of length shown obsolete and replaced. [d] 66% of length shown obsolete and replaced.

Paving standards are as follows: In Manhattan heavily traveled streets have 3 in. of asphalt on a 9-in. concrete base; other streets are paved with 3 in. of asphalt on a 6-in. concrete base. In Brooklyn heavily traveled streets have an 8-in. concrete base; otherwise the practice is the same as that for Manhattan.

In changing Area A to the master block layout, new sidewalks and curbs are required for all of the local traffic streets and new curbs for one side of the safety islands. Service roadways will have to be newly paved to the full widths and lengths indicated in Fig. 4. It is assumed that the surfaces of existing roadways retained in the master block scheme are in good condition but that curb replacement in connection with safety islands requires repaving of 10% of the road surface retained in the master block plan. Any other incidental repaving is considered a maintenance item rather than a permanent improvement.

Sewers (Item No. 3, Table 6).—There are no trunk sewers in the Manhattan communities, Area A and Units A_1 and A_2; but trunk sewer costs for Unit A_3 are estimated on a flat rate of 3 cents per sq ft of "buildable" area. Catch basins, inlets, and manholes are included in the costs since sewers serve as combination storm-water and sanitary drains. One half of the cost of sewers in boundary streets is charged against each community.

Standards in Manhattan call for sewers averaging 4 ft by 2.33 ft. In Brooklyn the average is 18 in., but, due to the long blocks, sewers in Unit A_3 are assumed to average 24 in. and are placed in service roadways.

The average age of sewers in Area *A* is seventy years and their useful life one hundred years, so that 70% of the sewers in existing streets that are retained in the public streets of the master block plan require replacement in either Unit A_1 or A_2. New surface drains are also required for the service roadways in the master block schemes.

Water Mains (Item No. 4, Table 6).—The costs of water mains include valves, fire hydrants, and manholes but exclude all house connections, which are made at the expense of the property owner. One half the cost of water pipes in the boundary streets is charged to each community, except for Unit A_3, where current practice would require the original installation of water mains in each of the service roadways of the master block plan, rather than a single pipe in the bed of boundary and interior streets.

According to records of the New York Department of Water Supply, Gas and Electricity, the average age of water mains in East Harlem is fifty years. The useful life of 12-in. and 20-in. lines is about one hundred years and for 8-in. pipe, seventy-five years. On this basis, one half the 12-in. and 20-in. mains and two thirds of the 8-in. pipes in Area *A* are obsolete and that portion retained in either Unit A_1 or A_2 would have to be replaced. Obsolete fire hydrants must also be replaced, and new and old hydrants relocated to conform to the master block plan.

Street Lighting (Item No. 5, Table 6).—Under current standards and prices lighting equipment for the neighborhood units costs $93.36 per light. The installation is estimated at $39.15 per light.

The city formerly rented street lighting equipment from utility companies; hence there is no city outlay for this equipment in Area *A*. Under present policy the city purchases and installs street lighting equipment. Both the new and rebuilt communities are therefore charged in full for this equipment as noted in Table 6.

Population Facilities.—The character of development and the size of the population that can be accommodated in a community create well-defined demands for parks and playgrounds, elementary and high schools, branch libraries, local health buildings, fire stations and police precincts, sanitation garages and section houses, sewage and refuse disposal plants, and rapid transit. These public services are termed "population facilities."

The obsolescence of existing facilities in Area *A* is determined by the present age and useful life of these improvements. The present age of most facilities is obtained from public records, but the age of libraries, fire stations, police precincts, and sanitation garages and section houses is assumed equal to the average age of existing schools in East Harlem, which is forty-three years. The useful life of these facilities is considered to be sixty years; hence they are 71.6% obsolete.

Parks and Playgrounds.—Table 2 shows that public parks and playgrounds account for 4.79 acres, which is equivalent to one acre for each 7,100 persons that can be housed in the community. The park land required in the neighborhood units is based on standards used by the staff of the Mayor's Committee on City Planning, which call for one acre for each 1,750 persons.

Closing certain interior streets in converting the gridiron street plan of Area A into the master block layout of Units A_1 and A_2 makes about 14.8 acres of land available for other purposes (see Fig. 4). Inasmuch as this land is now in the bed of publicly owned streets, it is assumed to be a city asset, which could be sold or traded for building purposes in exchange for equivalent acreage in appropriate locations for additional parks at no cost to the city.

In Unit A_1 the 4.79 acres (see Table 7) of existing parks plus 14.8 acres from discontinued streets would produce 19.59 acres of parks. The purchase of 2.46 additional acres would bring park acreage to the 22.05 acres required in Unit A_1. For Unit A_2 the existing park acreage plus the area of discontinued streets would provide the 19.02 acres needed for parks and would leave about 0.5 acre that could be used for other public purposes.

TABLE 7.—PARK NEEDS

Unit	Area, in acres	Land cost	Development ($7,000 per acre)
A	4.79	$1,734,000	$ 33,550
A_1	22.05	891,500	154,350
A_2	19.02	....	133,140
A_3	19.02	250,000	133,140

The extensive reconstruction involved in transforming Area A to a master block plan would necessitate the redevelopment of parks and the provision of new park equipment in either Unit A_1 or A_2. The existing park equipment in Area A, therefore, is assumed unusable in Unit A_1 or A_2.

Elementary Schools (Table 8(*a*)).—The number of children from each unit that may be expected to register in public elementary schools is estimated at 9.7% of the total population. The elementary school standard limits classrooms to thirty-five students, and the school needs of each unit are predicated on this average value.

TABLE 8.—EDUCATIONAL NEEDS

Area and units	(*a*) ELEMENTARY SCHOOLS			(*b*) HIGH SCHOOL			(*c*) PUBLIC LIBRARY			
	Student registration	Needed classrooms	Rooms replaced	Registration (seats)	Percentage of seats replaced	Unit cost (dollars)	Persons per branch	Ratio of use	Replacement ratio	Cost of branch (dollars)
A	4,462	127.4	....	1,840	....	1,200	50,750	90.6	....	166,600
A_1	3,740	106.8	79.6	1,542	24.3	1,200	50,000	77.1	71.6	89,600
A_2	3,227	92.2	65.0	1,331	24.3	1,200	50,000	66.5	71.6	89,600
A_3	3,227	92.2	....	1,331	....	1,200	50,000	66.5	....	126,520

Records of the Board of Education of New York City show that 79% of the classrooms available in East Harlem are in buildings that were erected prior to 1901. These buildings generally cover more than three quarters of plots averaging only 31,200 sq ft in area. It is assumed, therefore, that about 80% of the 127 classrooms available to Area A are obsolete so that only 27 classrooms in buildings less than forty years old are considered usable in Unit A_1 or A_2.

Unit A_1 needs about 107 classrooms, of which 27 are supplied by existing schools, and nearly 80 must be provided in new buildings to replace obsolete classrooms. Unit A_2 requires about 93 classrooms, and, by utilizing the 27 now usable in Area A, new schools containing only 65 classrooms need be built to meet the requirements of Unit A_2.

Since fewer classrooms are needed for Units A_1 and A_2, it will not be necessary to acquire more land for schools. If the new playgrounds required under minimum standards were located adjacent to school sites, both old and new buildings in Unit A_1 or A_2 would have more light, air, and play space than is now available in Area A.

Reports of the Board of Education indicate that the accumulated cost of land, equipment, and building for existing elementary schools in East Harlem average $13,650 per classroom. Elementary school costs in all of the neighborhood units are based on $21,000 per classroom, a city-wide average for schools constructed during recent years.

High Schools.—Approximately 4% of the population of each unit is expected to register in public high school. The standard requires the provision of one seat per student in an up-to-date school building.

On the premise that buildings more than forty years old are obsolete, the Manhattan high school plant measured in classrooms is 24.3% depreciated. This obsolescence factor is applied against the number of old seats needed in Units A_1 and A_2 to determine necessary replacement. The cost per seat for land, building, and equipment (see Table 8(*b*)) is a general average for high schools recently constructed.

Public Library.—The standard used by the Mayor's Committee on City Planning forms the basis for determining public library needs in the units.

The obsolescence of the branch library serving Area A is estimated at 71.6%. In either Unit A_1 or A_2 the need for library service is less than that required by Area A. It is assumed that the obsolete part of this existing branch must be replaced to the full extent of the indicated depreciation.

As evidenced by capital budget and program requests, branch libraries cost about $125,000 each for construction and equipment. This sum forms the basis for cost estimates in all communities, exclusive of plots 50 by 100 ft, which are assumed to cost 1.3 times the average assessed value. The charge to each community is determined by the "ratio of use" (see Table 8(*c*)), which, of course, is population expressed as a percentage of the capacity of a branch library.

Health Building.—The Health Department program for health education, preventive medicine, and local health service aims at the eventual provision of health center buildings throughout the city. The capacity of each health building under this program forms the "standard," and costs are obtained from the same source. The "ratio of use" (Table 9(*a*)) determines the charge against each community (see also Table 3(*a*)). The district health center now serving Area A is adequate for Units A_1 and A_2, and this building is so new that obsolescence is negligible.

Sanitation.—The present distribution of sanitation garages and section houses in each borough is assumed a satisfactory standard for all communities.

In Manhattan there is one sanitation truck for each 1,540 persons and one section house for each 32,300 residents. In Brooklyn the averages are 2,540 persons and 44,350 persons respectively. Data from the Department of Sanitation indicate that trucks require about 6,300 cu ft of garage space, which, at 35 cents per cu ft, amounts to $2,205 per truck. Section houses for the storage of street cleaning and sanitation equipment average $25,000 each.

TABLE 9.—HEALTH AND SANITATION

Area and units	(*a*) HEALTH BUILDING			(*b*) SANITATION BUILDINGS			(*c*) SEWAGE DISPOSAL			(*d*) INCINERATORS		
	Persons per building (thousands)	Ratio of use	Cost of building (thousand dollars)	Garages (dollars)	Section houses (dollars)	Replacement percentages	Persons per plant (thousands)	Ratio of use	Plant cost (thousand dollars)	Daily collection (cu yd)	Ratio burned (%)	Capacity (cu yd)
A	227.4	20.2	50.4	1.44	0.76	....	1,270	3.62	27,255	471.5	44.4	209.5
A_1	227.4	....	....	1.44	0.76	71.6	1,270	....	....	395.3	57	225.5
A_2	227.4	....	....	1.44	0.76	71.6	1,270	....	....	341.2	57	195
A_3	250.0	13.3	76.6	0.87	0.56	....	400	8.32	5,176	341.2	57	195

The per capita costs, estimated on the basis of current distribution of these facilities in each borough, are shown in Table 9(*b*). The total charges to each community are derived from the population and appropriate per capita value. In Area *A* depreciation is estimated at 71.6% and the charges in Table 3(*a*) for Units A_1 and A_2 are to cover replacements of obsolete plant only.

Sewage Disposal.—Sewage disposal is assumed essential in all of the communities, and the program for plants and treatment methods proposed by the Department of Public Works is taken as the standard. Costs are also derived from this source. Units A_1 and A_2 are served by the new Wards Island plant; Unit A_3 would be served by the proposed 26th Ward plant in Brooklyn.

The Wards Island disposal plant is practically new, and its capacity is adequate to serve either Unit A_1 or A_2. Hence, no replacement nor enlargement of existing sewage disposal facilities is involved in rebuilding Area *A* on the master block plan. Area *A* and Unit A_3 are charged according to the ratio of use (see Table 9(*c*)) of the rated capacity of the plants serving their population.

Refuse Disposal.—It is assumed desirable to incinerate all combustible material and to use only ashes and other inorganic refuse for land fill. Estimates made for the Mayor's Committee on City Planning show that 57% of the refuse is combustible material and the remainder is inorganic matter that can be disposed of by land fill. About 45% of the refuse from Area *A* is now incinerated (see Table 9(*d*)). It is assumed that land acquisition is not involved in disposing of the remaining refuse by the land-fill method.

The charges for refuse disposal are based on the use of incinerators of 750-ton daily capacity costing $1,500,000. Combustible material from each community is figured at approximately 600 cu yd per ton.

Estimated daily collection of all refuse is based on 3.2 cu yd per capita annually at 313 working days. The existing plant serving Area *A* handles 209.5

cu yd and is assumed 33% obsolete. An additional capacity of 16 cu yd is needed for the 225.5 cu yd to be incinerated in Unit A_1. New plant costs chargeable to Unit A_1 are $5,350 and replacement of obsolete part, $23,300. The 195-cu-yd capacity needed in Unit A_2 is 15 cu yd less than the existing plant serving Area A; this excess can be used for another community, and Unit A_2 is charged only for replacement of the obsolete part of the capacity of the old incinerator needed to serve this rebuilt community.

Fire Station.—The present distribution of fire stations in each borough is assumed adequate for the protection of residential neighborhoods. The existing facilities serving Area A are assumed 71.6% obsolete (see Table 10(*a*)) and to require replacement to this extent.

TABLE 10.—FIRE AND POLICE BUILDINGS

Area and units	(*a*) FIRE STATION NEEDS				(*b*) POLICE PRECINCT BUILDINGS			
	Persons per station	Ratio of use	Replacement ratio (%)	Cost per station (dollars)	Persons per building	Ratio of use	Replacement ratio (%)	Cost per building (dollars)
A	30,400	151.0	....	116,600	68,000	67.6	....	154,100
A_1	30,400	126.3	71.6	53,600	68,000	56.7	71.6	122,200[a]
A_2	30,400	109.3	71.6	53,600	68,000	48.9	71.6	80,600
A_3	37,400	89.0	....	76,520	92,400	36.0	....	115,540

[a] Additional land included in total replacement cost.

The total cost of stations is estimated at $75,000 per building plus 5,000 sq ft of land at 1.3 times the average assessed value of each community. The charge to each community, of course, is based upon the "ratio of use" shown in Table 10(*a*).

The fire alarm telegraph system now uses underground conduits and alarm boxes at approximately every alternate street intersection. On the normal gridiron layout, this calls for twenty alarm boxes per community. The master block plan, however, needs only sixteen alarm boxes per unit. Installation costs, at $1,000 per box, are $20,000 for the gridiron street plan and $16,000 for the master block plan. One half of the twenty existing boxes in Area A are assumed obsolete, but four of the boxes not needed in Unit A_1 or A_2 have a salvage value of $200 each, which reduces the replacement cost to $7,200 in each of these units.

Police Precinct.—The standards for police protection for all communities are also based upon the present distribution of precinct buildings in each borough. The obsolescence of police stations serving Area A is the same as fire stations—namely, 71.6% (see Table 10(*b*)). Replacement to this extent is necessary for Units A_1 or A_2. Most of the old police precincts occupy plots 50 ft wide, but garages for motor equipment adjacent to new stations require lots 100 ft wide. In Unit A_1 the additional land must be acquired. After providing for park needs in Unit A_2, however, sufficient land would be left over from discontinued interior streets to allow for the larger police station lot.

The costs charged to each community (see also Table 3(*a*)) are based on the respective ratios of use, with buildings at $112,500 each and land at 1.3 times the average assessed value.

Rapid Transit.—This study assumes that adequate transit service is essential to the proper functioning of the neighborhood unit communities. The measure of adequate transit service during the morning rush hours (see Table 11) is predicated on "reasonable" carloadings, as defined by the Transit Commission, and sufficient capacity on lines to transport the passengers contributed by each unit with out exceeding this "reasonable" load.

TABLE 11.—MORNING RUSH-HOUR PASSENGERS

Area and units	Percentage of population	Total load	I.R.T. subway	Independent subway	Elevated lines
A	14.4[a]	5,178	3,791	.....	1,387
A_1	14.4[b]	5,450	4,140	1,310	.....
A_2	14.4[b]	4,705	4,140	565	.....
A_3	18.8[b]	6,255	.....	6,255	.....

[a] Ratio of actual population. [b] Ratio of population at full occupancy of housing.

The "reasonable" carload (about 3 sq ft per standing passenger with all seats filled) does not represent the most desirable or convenient transportation, but it is a practical basis for measuring line capacity. Besides carloading, two other factors are involved in determining the capacity of transit lines serving each unit: (1) The number of cars per train, and (2) the headway between trains during the morning rush hours. Adequate transit service, therefore, must provide sufficient capacity to carry the passengers contributed by each unit, as well as by the remaining half-mile zone served by each line, without exceeding "reasonable" carloadings during the morning rush hours on any line into central business districts. In 1935 the Interborough Rapid Transit Company (I.R.T.) was carrying loads during the morning rush hours that are estimated to be 1.2 times greater than the reasonable capacity of the line serving East Harlem. As a result, the actual number of persons living in Area *A* is used to determine rush-hour loads. In the neighborhood units, the population that could be housed at full occupancy of dwellings determines the loads and the capacity required.

Table 11 shows the estimated rush-hour passengers contributed by each community and the number using each rapid transit line. Of the total passengers contributed by Area *A*, only 83% of those using the I.R.T. subway are assumed within the capacity of this line because of the present overcrowding. With certain remedial measures it is believed possible to increase the capacity of this line by 1.3 times during the morning rush hours. This would increase the present 3,165-passenger reasonable capacity of the I.R.T. subway available to Area *A* to 4,140 rush-hour passengers.

In rebuilding Area *A* it is supposed that the obsolete elevated lines serving East Harlem will be demolished and that remedial measures will be undertaken on the I.R.T. subway. Thus, all traffic from Units A_1 and A_2 must use subway lines, including a new subway to replace the Elevated Railway.

Unit A_1 will contribute 5,450 rush-hour transit passengers, of which 4,140 are expected to use the I.R.T. subway, and 1,310 passengers will have to be accommodated on the new subway line that will be needed after demolition of the Elevated Railway. Unit A_2 is expected to contribute 4,700 passengers during the morning rush hours. With the reasonable capacity available after remedial measures, the I.R.T. can serve 4,140 of these people, and the new subway line will accommodate the remaining 565 passengers from Unit A_2.

The Elevated line in East Harlem was built at private expense and cannot be charged against Area A. On the basis of total city contributions to the I.R.T. subway construction, it is estimated that the city's capital outlay averages $437 per passenger carried during rush hours in 1935. According to studies of the Mayor's Committee on City Planning, remedial measures would increase the capacity of the I.R.T. by 1.3 times at a cost of $147.50 for each passenger that could be carried over and above the present reasonable capacity of this line. Assuming a total of $815,000,000 as the cost of the Independent (including sections under construction), and the rated capacity used in the Mayor's Committee Rapid Transit Study, the city will have spent $1,132 for each passenger that this system can carry into work centers during the morning rush hours. These estimates of capital costs to the city per passenger carried during the morning rush hours on each line serving the several communities determine rapid transit charges summarized in Table 3(*a*).

ESTIMATES OF ANNUAL EXPENSES

This section of the Appendix outlines the methods used in estimating the annual expenses for operating and maintaining the public services provided in each community.

Except as otherwise noted, unit costs are based upon the most recent information available from the operating agencies. The per capita costs are generally derived from the total annual expense and the estimated population actually living in the city. Therefore, the "actual" population living in the several communities, rather than the "demand" or potential population that would result from 100% occupancy of residential quarters, is used in determining annual expenses that are based on per capita costs. The estimated yearly expenses charged to each community are summarized in Table 3(*b*) by item.

Street Cleaning.—Annual costs of street cleaning average 27.3 cents per sq yd in Manhattan and 13.1 cents in Brooklyn. Snow removal averaged 20.3 cents per sq yd over a five-year period. Computed for the roadway area, there are 157,000 sq yd of roadway to be cleaned in Area A and 142,520 sq yd in each unit. On the basis of full street width there are 263,884 sq yd to be cleaned of snow in Area A and 187,969 sq yd in each unit.

Sewer Maintenance.—The unit cost of cleaning sewers in Manhattan during 1938 was $203.50 per mile and $8.60 per catch basin. Since data were not available for Brooklyn, the unit cost is the same as Queens—namely, $102.50 per mile of sewer and $8.60 per catch basin.

There are 6.76 miles of sewers and 80 basin manholes in Area A, but only 2.92 miles of sewers and 36 basin manholes in Units A_1 and A_2. Because pipe is placed in service roadways, Unit A_3 has 5.52 miles of sewers and there are 36 basin manholes.

Water Mains.—The annual expenses per mile of pipe for water-main maintenance include 70% of the motor vehicle operations cost for mains in existing streets, regardless of pipe size. The age of mains is not considered a factor because unconsolidated fill tends to cause new mains to break more frequently than old pipes. The annual maintenance expense in Area *A*, and Units A_1 and A_2, is computed at the Manhattan average of $884 per mile of pipe. The cost in Unit A_3 in Brooklyn is based on $449 per mile of pipe per year. Pipe length is given in Table 6.

Street Lighting.—In Area *A* the annual rental of street lighting equipment from the utility companies is estimated to average $25 per light. In the neighborhood units the city would install and maintain its own equipment. Recent operating experience indicates that the annual expense would be $8.34 per light.

Parks and Playgrounds.—An examination of the Comptroller's Report indicates that appropriations for the operation and maintenance of parks and playgrounds amounted to more than $8,800,000 during 1938. This appropriation represents an average cost of about $525 per acre of park, including all facilities under the jurisdiction of the Park Department. This unit cost is used in estimates of annual expenses in all communities.

Elementary Schools.—The average cost per classroom for physical operation and maintenance of elementary and junior high schools as reported for 1937 is $387 in East Harlem (Area *A*); but the city average approximates $400 per classroom, which value forms the basis for estimates in all neighborhood units.

The cost of instruction, excluding general administration, averages about $4,000 per classroom for the entire city. Similar data are not available by school district and, therefore, instruction costs for all communities are based on the city average.

High School.—The annual expenses for instruction and high school building maintenance, shown by reports to approximate $159 per student registered, are the basis for the estimates given in Table 3(*b*).

Public Library.—Requests for public libraries submitted in connection with the capital budget indicate that the annual operation and maintenance costs average $35,000 for the type of branch that serves residential districts. With this value as a base, costs are allocated to each community on its "ratio of use" of library facilities.

Health Building.—Each community is charged with its proportionate share of the annual expense of maintaining and operating health center buildings, as given in the Health Department program submitted to the City Planning Commission. The expense in the East Harlem district (Area *A*, and Units A_1 and A_2) is given as $13,970 per yr, and in the district serving Unit A_3 the total cost is $16,210.

Fire Protection.—Estimates of yearly expenses for fire protection are based on the following per capita charges:

Borough	Dollars per year
Manhattan	4.19
Brooklyn	3.16

These values are derived from reported costs for operation, including equipment, telegraph, buildings, and personnel in the smaller stations, which are assumed typical for residential districts.

Police Protection.—The annual charges for police personnel, motor and other equipment, and building maintenance average $3.22 per person living in Brooklyn and $6.90 per person living north of 80th Street in Manhattan.

Refuse Removal.—The annual maintenance of sanitation garages and section houses, as well as the costs of collecting refuse, are included under "refuse removal" expenses. These expenses average $2.17 per person in Manhattan and $2.02 in Brooklyn. Application of these figures to the population of each community produces the estimates summarized in Table 3(*b*).

Sewage Disposal.—The costs of sewage treatment given for the various plants in the "Tentative Plan for Sewage Disposal" prepared by the Department of Public Works and submitted to the City Planning Commission are used to determine the total operating expenses for each plant. The estimated operating expenses for the Wards Island plant are $650,400 per yr, and for the 26th Ward plant, $213,100 per yr. Each community is charged with its share of the annual expenses in proportion to the "use ratio" of plant capacity.

Refuse Disposal.—The cost per cubic yard of material incinerated is about 20 cents in Manhattan and 18 cents in Brooklyn (see Table 12). The disposal of ashes and other non-combustible material is assumed at about 10 cents per cu yd in Manhattan and approximately 6 cents in Brooklyn. Table 12 shows the total annual collection of refuse in square yards, the disposition by community, and the unit cost (see Table 3(*b*) for the total annual expenses).

TABLE 12.—REFUSE DISPOSAL EXPENSES

Area and units	Annual (cu yd)	INCINERATED		LAND FILL		DUMPED	
		%	Cost[a]	%	Cost[a]	%	Cost[a]
A	117,477	44.4	20	4	10	51.6	15
A_1	117,477	57	20	43	10	....	..
A_2	101,373	57	20	43	10	....	..
A_3	101,373	57	18.1	43	6.4	....	..

[a] Cents per cubic yard.

Debt Service on Rapid Transit.—This study considers the capital costs of rapid transit a proper charge against communities in proportion to the line capacity used. The annual costs of operation and maintenance of the lines, however, are paid out of operating revenues. Under existing operating conditions these expenses are not met by the city and are not charged against the communities. The city does contribute substantial sums to service its outstanding rapid transit debt. Accordingly, debt service on that part of the subway improvement costs allocated to each community is charged as an annual expense in Table 3(*b*).

The capital cost shown in Table 3(*a*) is assumed to be financed by fifty-year corporate stock requiring annual payments of 4% interest and instalments to a sinking fund earning 3% for amortization of principle.

DISCUSSION

Donald M. Baker,[9] M. Am. Soc. C. E.—The problem of rehabilitating residential areas where housing has fallen below the standards for which it was originally developed is one that has attracted considerable attention during the two decades since 1920, and will achieve much greater importance in the future.

During past periods of relatively high rates of population increase in metropolitan areas, land area devoted to residential housing likewise increased comparably. New housing was provided primarily for residents in the high-income and upper middle-class income brackets, whose vacated dwellings were then occupied by those with lesser incomes. With continued growth, these in turn moved on, to be replaced by a succession of residents in progressively lowering economic levels. Ultimately, an area was occupied by those in the lowest income brackets unless, as sometimes happened, such housing was located adjacent to an expanding commercial district. Then commercial or light industrial uses would invade the area, occupying the former residential buildings, or replacing them with newer buildings specifically constructed for particular uses. Until about 1920, little attention was given to the progressive "blighting" of older residential districts. Such phenomena were accepted as a normal result of metropolitan growth. Owners of property in such areas maintained hopes that expansion of commercial or industrial districts would in time reach their property, and give it values based upon such uses.

Community planning, as it is now beginning to be practiced, based upon the scientific method of collecting, analyzing, and interpreting factual data relative to growth and decay, developed a realization that the progressive decay of such areas was an effect, the causes of which were subject to determination, and that in many instances remedial measures were possible. Without question, economic losses due to "blighting" are very great, not only to owners of property within "blighted" areas, but likewise to entire communities where such property exists, and to residents of such communities.

Owners of such property experience not only reduction of value of land, because of lowered rentals upon improvements, but likewise a loss of adequate return upon that part of the improvement—the foundation and the shell of the structure—whose physical life, if it is well arranged and soundly constructed, may range as high as one hundred or more years. Reserves for depreciation and obsolescence are seldom if ever set up in individually owned properties, and are more or less impracticable. Community losses include a reduction of taxable values and loss of a part of the public's investment in improvements and services. These usually have a useful physical life in excess of the life of the area served for any but the lowest type of residential housing or, in time, they develop excess capacity due to population loss in such area.

Loss to individuals includes an increase in taxes to support cost of improvements and services originally provided for the "blighted" area, which fails to carry its share of such cost because of lowered taxable value, and loss to merchants and property owners in business districts serving the "blighted" areas. There is also the expense and loss of time caused to those who, daily or frequently, must travel between outlying residential areas and the central business district a greater distance than they were formerly required to travel.

---

[9] Cons. Engr., Los Angeles, Calif.

Movement into new housing is caused by both "pulling" and "pushing" forces. Improvement in financial circumstances, attraction of new surroundings and environment, and more modern conveniences all initiate the movement away from established housing for those who can afford it. A "vacuum," slight in amount, is created, which tends to "pull" into the area residents in lower economic levels who can afford to move up the scale somewhat. Soon environment and neighbors have changed to a point where residents who were not "pulled" out of the area are "pushed" out. The cycle is continuous, and may require many years to change the character of a district from a high to a low level. In general, however, the rate of obsolescence and blighting of a residential district varies directly with the rate of population increase in the community as a whole.

With a reasonably high percentage rate of population increase, the supply of persons required to fill up the vacuum created by the outward flow of residents from older districts usually exists all through the scale. The 1940 federal census brought home to many people, however, the fact that most metropolitan areas, as well as the nation as a whole, are fast approaching a static condition in regard to population, and that former rates of increase will not be maintained.

This condition will undoubtedly bring the problem of the "blighted" area into a far clearer focus. Unless American society becomes far more static than it has in the past, with barriers between those in various economic strata becoming far more inflexible, there will always be a large segment of the population who will yearn for, and also be able to achieve, better housing, surroundings and environment, modern conveniences, and everything else that goes with improved circumstances. The demand for new housing will continue; and the "blighted" areas will increase also, but the supply of residents for these latter areas will not be forthcoming as it has in the past, and decay and loss of values therein will be accelerated.

New housing, as now produced, is usually supplied around the periphery of present developed areas. It entails the expense of the many facilities indicated by the author. These expenses are usually a community obligation. Arresting decentralization of population through rehabilitation of areas now in this condition, or approaching it, means large annual savings in dollars and cents to the community, and therefore to its taxpayers.

There is another side of this problem of rehabilitation, however, which pertains to the owner of property in a "blighted" area, who might desire to undertake rehabilitation, or to the investor who might desire to finance it. In many instances, rise in price levels over a long period, and likewise rise in values due to general increase in population of most communities, have reduced losses due to depreciation or obsolescence when property has changed hands. The temptation to spend all revenues received from rentals, except that immediately necessary for routine expenses, maintenance, taxes, interest, and amortization of loans, is increased by the feeling of rising valuations offsetting, at least to a degree, depreciation and obsolescence.

An owner, or an agency contemplating development of new housing to replace old existing housing in a blighted area, is faced with the following problems:

(1) A large area must be acquired if a proper environment is to be created, such area ranging from at least 40 acres to possibly several times this extent. Demolition of a few existing structures, and their replacement by new and modern buildings, will not create environment.

(2) To secure control of an adequate area, many individual properties must be assembled and purchased, or condemned, entailing large outlay of capital for land alone.

(3) When the cost of buildings is added to the capital investment required for land alone (which in a project of this nature would include land and obsolete improvements), any such project takes on very large proportions.

(4) When such investments are constructed upon unimproved land in peripheral localities, the owner's investment usually includes the cost of an unimproved site, of buildings, a certain amount of landscaping, and those public improvements and services not usually provided by the community or existing public utilities. It is questionable in many cases if the increased rentals received from new developments in a rehabilitated area will support the added site cost in such an area.

For years sociologists have stressed the economic losses resulting from substandard housing—losses resulting from sickness, from crime developed in such housing, and from increased costs of fire and police protection. These losses have even been evaluated in terms of dollars and cents. So far, research has failed to develop a type of low-cost housing within the reach of those in the lowest economic circumstances, without some form of subsidization. The propriety of public subsidization of housing for this part of the population has recently been accepted, and many low-cost housing projects have been constructed or are contemplated.

With the definite community savings as shown by the author, which are affected by rehabilitation of "blighted" housing through site planning, and construction in accordance with new and modern standards, the writer poses this question: "Would it not be a sound investment if such projects likewise were to receive public subsidization from the community, at least to an extent which allowed the increased burden of added site cost to be overcome?"

The paper is a distinct contribution to the literature of this subject, made in a language that businessmen understand—that of dollars and cents.

Howard Whipple Green,[10] **M. Am. Soc. C. E.**—With the United States approaching a stable population and its large cities beginning to realize that their population increases will be much more moderate in future decades, with several large cities for the first time showing actual decreases in population while their suburbs still continued to increase, with fewer and fewer persons left in the central city to bear larger and larger tax burdens, with industry and commerce showing indications of decentralization, and with slum and blighted areas increasing in extent and severity, the problem of rebuilding cities in the United States ranks near the top of the list of important things to be given attention following the present national emergency.

---

[10] Secy., Cleveland Health Council; Director, Real Property Inventory of Met. Cleveland, Cleveland, Ohio.

A possible solution to this serious problem of the depopulation of the center of most large American cities with increases in population around the periphery is indicated by the detailed calculations presented in this paper. Although all computations presented are naturally based upon New York City, standards of land use, and unit costs of public improvements and services, similar computations made in smaller cities with different standards of land use and different unit costs may demonstrate even more striking differences between the rehabilitation of existing blighted areas, the entire rebuilding of these areas, and the relocation of their populations on vacant land in outlying sections within or beyond their corporation limits.

The basic facts made available in Cleveland, Ohio, by the continuous Real Property Inventory started in October, 1932, augmented by unit costs of public improvements and services, make such a study possible with a minimum amount of effort.

Cleveland being built horizontally, contrasted with New York's vertical pattern (especially the Borough of Manhattan), doubtless will show quite different factors. However, it is as true in Cleveland as in New York that the public utilities that were complete in the section designated as census tract J-1 (with a population of 6,114 in 1910), which decreased to 493 in 1920, to 49 in 1930, and to 3 in 1940, were of no assistance to census tract T-8 with a population of 59 in 1910, which increased to 1,557 in 1920 and to 10,577 in 1930, decreasing to 9,986 in 1940; nor were the schools, hospitals, and churches, or the retail stores, water mains, sewers, paving, gas lines, and electric and telephone networks serving the 6,114 inhabitants of census tract J-1 in 1910 and quite useless to the 3 persons living in this area in 1940 of any aid to the suburb of University Heights, which increased from a population of 156 in 1910 to 5,981 in 1940. Such a shifting of population is one problem during periods of rapid population expansion accompanied by proportional expansions of industry and commerce, but it is quite another as a stable population is approached.

T. T. McCrosky,[11] M. Am. Soc. C. E.—Many large-scale real-estate developers have made detailed cost studies of the relative economics of private building operations on high-priced improved slum land versus low-priced raw land; but their studies do not include consideration of the costs to the public that enter into their contemplated developments. To the writer's knowledge, Mr. McHugh's paper is the pioneer research in the field of cost of public services made necessary by large private residential projects. As a former colleague of the author, it was the writer's privilege to follow this study closely during the months that it was being conducted without, however, participating directly in its progress.

---

[11] Executive Director, Chicago Plan Comm., Chicago, Ill.; formerly Director of Planning, Dept. of City Planning, New York, N. Y.

Similarly thorough analyses could be made for other cities, with different unit costs and appropriate modifications in the assumptions; but the resulting quantitative comparisons would assuredly be of the same general order of magnitude, differing only in degree. The case is proved by this study. It costs the public very much more to provide services for outlying developments than for equivalent redevelopment projects in "near-in" locations, where many satisfactory public facilities already exist. Whether it be 50% to 90% more per person housed, as computed by the writer (for Units A_1 and A_2, where rapid transit charges are excluded), or some moderately lesser or greater figure, is of secondary importance to the fundamental conclusion that it is manifestly uneconomical from the public standpoint to encourage the decentralization of cities.

The great difference in public costs between development of areas with existing transit facilities and areas where new transit lines must be provided is clearly revealed by the author. The moral is inescapable that the least a city should do is to discourage new large-scale building on outlying vacant land that does not have, but will require, transit service.

It would be very valuable to have an extension of this study, in order to develop consolidated comparisons of capital and operating figures for the combination of public services plus private project costs. The differentials of public outlay are both capital and current account. They result from the cost of duplicating facilities and services already existing at the central location. These have been very thoroughly and ably analyzed by the author. The principal differentials of private outlay are capital items. They are the price of land, the expense of assembling it, the cost of the improvements, and the cost of the demolition of slum buildings to make way for the new project. Unfortunately, slum buildings do not tumble down like the walls of Jericho at the summons of a Joshua.

With a consolidated cost comparison, it would then be fruitful to study the feasibility of offering some partial public subsidy to the private builder to encourage him to redevelop slum areas. This could be scaled so that the costs to the taxpaying public, including subsidy, still would be well below what they would aggregate if the builder developed outlying raw acreage. In practice, the subsidy might often take the form of giving title deeds to tax-foreclosed properties, which were foreclosed because they yielded no taxes and thus made no return to the public, and which can never make a return unless transferred to a private owner for sound redevelopment. Another form of subsidy that costs the public nothing is to deed unnecessary street land to building corporations. Partial or limited tax exemption is also "cheap at the price," inasmuch as slum land is notoriously delinquent in most cities. If the public actually collects moderately more taxes from the new project than it did from the substandard properties that are replaced, it is "ahead of the game."

When peace comes, urban America will need a coordinated program for city rebuilding, embracing all price and rental brackets and clearly determining the extent and limits of public and private participation in each bracket. Preparation of this program is the responsibility of the technical professions in the building field. Mr. McHugh's paper is a valuable contribution to the economics of this broad-scale approach to urban redevelopment.

F. DODD MCHUGH,[12] ESQ.—There have been vast changes in the world since the paper on "Cost of Public Services in Residential Areas" was first published. The United States is at war, and the Nation has passed from a defensive phase of preparing for some vague eventuality into a period of vigorous war activity. Its main efforts are directed toward winning a most difficult war to secure freedom. Many individuals are engaged directly or indirectly in the war effort or in civilian defense activities.

Under the circumstances, it may seem like "fiddling while Rome burns" to discuss such matters as public outlays for municipal services. Upon many recent occasions it has been said, however, that one must not only win the war but the peace. To win the peace the people must define their goals and do an extraordinary amount of enlightened planning while the war is being fought.

When the phenomenal efforts of the United States and its Allies have brought peace to the world, most of the old problems will remain and a host of new ones will have appeared. What will the Nation do about some of the now familiar domestic problems? Plans are already in the making for the readjustment of private business after the war, for public works programs, and, among other things, for urban redevelopment. It would seem the logical time to discuss public outlays for municipal services, if such investigations can aid in the clarification of policy and in the formation of postwar action programs.

Planning for the Postwar Era.—There is already wide recognition of the necessity for careful planning for the postwar period, and many public and private agencies are doing research in a variety of fields.[13] The executive branch of the federal government has stated broad objectives and initiated investigations and long-range programs directed toward meeting the future social and economic needs of the Nation. In transmitting to the Congress the "Development of National Resources—Report for 1942," prepared by the National Resources Planning Board, the President stated in part,

> "Plans and programs to win the war and to win the peace must grow out of our common national purpose and with democratic participation in planning by all of us. Through efforts to state our objectives and public discussion of their merits, we play our parts as free citizens."

This report suggests for discussion the following principal objectives of postwar planning: Full employment and maintenance of the national income at not less than $100,000,000,000 a year, without lowering working standards; decentralization of postwar activities and full use of free enterprise in cooperation with national and government leadership; and individual realization of security, opportunity, and the basic freedoms. It also suggests upbuilding America as the keynote of a postwar program,

---

[12] Director of Planning, Dept. of City Planning, New York, N. Y.

[13] See the survey on "Post-War Planning in the United States," by George B. Galloway, The Twentieth Century Fund, New York, N. Y., 1942.

> "* * * including both development of our national resources adding to the National Estate, and service activities, which will increase the vitality, health, skill, productivity, knowledge, and happiness of the American people, and thus together end unemployment and add to our wealth and well-being."

This is not the place to enlarge upon these objectives, but an outline of them indicates the breadth of thinking in the federal approach to winning the peace on the domestic scale. The National Resources Planning Board is correlating plans and programs under consideration in many federal, state, and private organizations for postwar full employment, security, and building America. Among other things, it not only furnishes aid in various phases of the war effort, but it also brings together 6-yr programs of federal agencies and aids in developing programs of useful public improvements and services planned by state and local governments. With the necessary detailed plans completed, this great reservoir of public works can help to absorb the men and industry that will be demobilized after the war.

The New York City Planning Commission is proposing that the 1942 Capital Budget be amended to provide funds for the planning of a postwar program of public works. Some funds for general planning studies, sites, preliminary plans, working drawings, and specifications are provided in the 1942 Budget. The proposed Post-War Works Program would expand the reserve of projects that can be undertaken, whenever men, materials, and funds are available, by completing plans for a considerably enlarged number of desirable municipal improvements.

Regardless of the as yet uncrystallized results of current discussion and planning for postwar activity, one can readily agree that any action programs that may be developed cannot do less than promote the conservation of human and natural resources in a society of free men. It is perhaps a poor commentary, but human society seems able to achieve its greatest organization and productivity in periods of national and international stress. In the intervening peaceful times, the extraordinary cooperation attained in emergencies fades. There is no actual reason, however, why a democratic system cannot function equally as well for peace if it can agree upon broad objectives and mobilize the creative, organizing, and productive abilities of its people to promote the general welfare.

In the discussion, planning, and execution of any postwar program, the individual as well as the system of private enterprise must make substantial contributions. Government may have to give new forms of assistance and some direction in coordinating private action with public programs, but enlightened free enterprise must play a major part in attaining anything like full employment, security, and the upbuilding of America in the postwar era.

Urban Rebuilding.—There will be many possibilities for new cooperative activities after the war, including urban redevelopment. More than one half the population of the United States lives in urban areas, and about 48% of it in some 140 metropolitan districts. The 1940 census data clearly reveal that the rate of population growth in the United States is slowing down to the point where it will probably approach stabilization during the life of the present generation. Urban and metropolitan areas are following this general trend, with a few notable exceptions. Consequently, there is a definite need for ordering the towns and cities of the Nation on a more up-to-date and efficient basis for working and living if they are to serve their functions properly in an era of population stability. The social and economic losses due to overexpansion, blight, and obsolescence must be arrested. Existing transportation facilities should be improved and integrated with the transportation advances that undoubtedly will follow the war; obsolete housing should be replaced by large-scale residential neighborhoods designed to improve living conditions and to stabilize the residential character of communities on a high social level.

These notions are not new; they are being discussed throughout the Nation. The importance of coordinating public and private plans and actions in urban rebuilding is obvious. Similar cooperative efforts are already under way in England. Such a program requires the definition of national and local objectives, and the development of new approaches and techniques to draw the broad outlines and fix the tempo within which the gigantic task of city rebuilding might proceed.

Public Costs and Other Factors.—The "Cost of Public Services in Residential Areas" is one of many kinds of investigations needed, and in fact it was undertaken as part of a larger scheme of approach to municipal problems in New York City. As mentioned in the discussions, these urban problems are much greater than the relative costs of public facilities in certain types of residential development.

Mr. Baker has noted the economic losses of individuals, property owners, and the public at large due to urban blight and decentralization. Incidentally, one phase of the original cost study indicated that overexpansion and duplication of public services in residential areas are costing the City of New York at least $40,000,000 annually for operation and maintenance. This is a rough estimate, to be sure, but it suggests the extent of economic loss suffered by the public as a result of blight and decentralization within the city's boundaries. Mr. Baker also mentioned the problems of land assembly and high site cost in connection with large-scale rebuilding. He asks if rents in a rebuilt area can support the high site cost and suggests that it might be a sound investment to subsidize such residential projects, at least to the extent of overcoming the burden of high land acquisition costs. Here is one of the greatest obstacles to city rebuilding. It would appear questionable that even one community could be rebuilt privately on a large scale and become self-supporting without public financial assistance because the rentals that its tenants could afford are almost certain to be insufficient to cover the high site cost plus the expense of new dwelling construction. The ease of land assemblage and its relatively low cost in suburban and outlying urban areas permit profitable private developments, and account in some measure for the continued physical expansion of cities even after population growth is drastically reduced.

Mr. Green ranks rebuilding problems near the top of the list of important things to be given attention following the present national emergency. The writer agrees with the ranking and with the absolute need for concentration on the war effort, but he is convinced that means must be devised and plans developed for urban rebuilding before the war is over. Otherwise, the Nation will be in a less favorable position in winning the peace. Had Mr. Green presented such computations of public costs in Cleveland, they would have been a welcome addition to the paper. Its continuing Real Property Inventory puts Cleveland in the enviable position of knowing of current changes, and the data thereby available make such investigations as a cost study relatively easy.

Mr. McCrosky suggests that the cost study should be extended so as "to develop consolidated comparisons of capital and operating figures for the combination of public services plus private project costs." He also mentions the problems of site acquisition and suggests an investigation of the feasibility of offering some kind of partial public subsidy to the private builder as encouragement in the redevelopment of slum areas. He makes an excellent point in stating that, since tax delinquency is prevalent in slum areas, limited tax exemption would be justified if the actual tax yield on rebuilt projects exceeded the taxes collected from the replaced substandard properties.

In the section of the city represented by old Area *A* of the cost study, it was found in 1938 that some 23% of the properties were tax delinquent. On the basis of this delinquency ratio and a basic levy of 2.75 on an assessed value of 29.8 million dollars for residential property in old Area *A*, the city collected about $630,000 in taxes from housing in this area. Assuming for the moment that new housing in rebuilt Unit A_2 is assessed at the same value as the existing residential properties (29.8 million) and the tax levy remains at 2.75, collections should average 98% of levy. On this basis the tax yield would approximate $820,000 per yr, which amount is 1.29 times current collections in old Area *A*.

The total costs of land and new housing in rebuilt Unit A_2 may be expected to exceed the present assessed value of existing dwellings in old Area *A* by an amount which would be determined by site and construction costs. However, if the assessed value of new housing in Unit A_2 were held at the same level as existing dwellings in old Area *A*, the private developer thus would receive a form of public subsidy; but the city's debt incurring and taxing powers would not be curtailed by a reduction in assessed value and, as Mr. McCrosky states, the city would be "ahead of the game," in so far as taxes collected on the new housing exceeded the present yield of taxes levied.

The discussions have been most profitable. The writer was disappointed, however, that the assumptions and techniques of the cost study were not subjected to a more critical evaluation. The setting given to the study and the questions raised in the discussions lead to further comment on investigations undertaken since completion of the original cost study in 1939. In this connection it should be made clear that the material contained in this closing discussion, as well as in the paper, does not in any respect represent the opinion nor the policy of the New York City Planning Commission or of the Department of City Planning.

Current Studies.—There is considerable evidence of a widespread approach to the solution of urban problems. The following is by no means a complete summary, but it is illustrative of current trends. In its "Urban Progressive Planning Project" the National Resources Planning Board is attempting to establish procedures for the progressive planning of required urban facilities. The Federal Housing Administration (FHA) has prepared *A Handbook on Urban Redevelopment for Cities in the United States.* It contains timely suggestions for procedures in an integrated long-term program for dealing with slums and blighted urban areas. The Illinois and New York State legislatures have enacted urban redevelopment laws that attempt to attract private capital into the rehabilitation of cities.

The findings of the cost study indicate that large-scale rehabilitation of old central apartment districts is economically feasible and preferable to new developments in outlying sections in so far as city expenditures are concerned. The paper concluded with a suggestion that essential studies of the private costs involved, and of the procedures to be used in large-scale redevelopment of entire neighborhoods, be undertaken immediately under a joint private and public sponsorship. The study showed that, if all the persons living in old Area *A* were rehoused on the same site, the new dwellings in Unit A_1, at an average height of six stories, would cover 68% of the residential land and the net density would be 731 persons. In setting up Unit A_2, it was assumed that apartments averaging six stories and covering 50% of the residential land, with a net density of 540 persons, would produce a better living arrangement and that thus Unit A_2 would be subject to a much lower rate of obsolescence than Unit A_1. The costs per person housed were also found to be lower in Unit A_2 than in Unit A_1. This finding suggests that there may be an optimum density, at which public costs per capita would reach a low point, in the rebuilding of old Area *A*.

A study was made to ascertain this population density or range of densities. Regardless of other considerations, it was assumed that old Area *A* might be rebuilt to house a varying number of people, and the calculations were based on the same suppositions and technique used in the original study. (The computations were made under the author's direction by Roger W. Loewi, "Interne" in the Department of City Planning during the summer of 1940.) A part of the results are given in Table 13, which shows that the lowest per capita city expenditures are attained in rebuilding old Area *A* at a density of 324 persons per residential acre. This particular 160-acre community, identified as Unit *C* in Table 13, could house more than 24,500 people in buildings covering 30% of the residential land at an average height of six stories. The per capita cost varies within narrow limits, however, as between the communities designated as Units *B*, *C*, and *D*. Although not shown in Table 13, it was found that per capita costs for developments with densities greater than

731, and less than 108 persons per residential acre, increase at a more rapid rate than the change in density. This indicates that, other things being equal, it would be better from the point of view of public outlays required to rebuild old Area *A* as a modern community within a density range of about 250 to 430 persons per residential acre. This possibility raises an entire series of questions concerning the community's place in the scheme of things, such as the desirable urban pattern for the entire city and its parts, as well as the objectives, techniques, and standards for planning the redevelopment of American cities—in this case the residential sections of Manhattan in New York City.

TABLE 13.—CITY EXPENDITURES PER PERSON, BASED ON APARTMENTS AVERAGING SIX STORIES IN HEIGHT
(With Transit Charges)

Rebuilt community	Proportion of land covered (%)	Persons per residential acre	Improvement (dollars per person)
Unit A_1	68	731	163
Unit A_2	50	540	119
Unit *B*	40	432	96
Unit *C*	30	324	95
Unit *D*	20	216	98
Unit *E*	10	108	110

Private Costs in Rebuilding.—Mr McCrosky's suggestion that the cost study be extended to develop consolidated comparisons of capital and operating figures for the combination of public services plus private project costs is difficult to carry out, due to a multiplicity of variable factors. Several attempts, made along these lines, have so far failed to produce satisfactory results. Complex problems are involved and available data are insufficient. One angle of approach might be somewhat as follows:

The people now living in the specimen community, old Area *A*, have different incomes—not all of them are in the lower income category. In rebuilding such obsolete sections on a large scale, it will be necessary to make provision for families of varying income. Assume that in the present case the engineer is concerned with an average community that will accommodate all groups. With this assumption it is possible to deal with the average rental that people can afford to pay. In New York City this sum is approximately $520 annually per family, which represents the average "demand." What can the private developer supply to meet this demand?

The answer to this question is conditioned in large measure by the capital outlay required of the private developer and the annual carrying charges on the completed project. For purposes of discussion, assume that the operation and maintenance, including insurance and a vacancy allowance, can be held to an average of $150 per dwelling unit. On the basis of the $520 average annual income received for each dwelling unit, and an annual cost of $150 for operation, etc., the private developer would have $370 left to cover taxes, capital charges, and interest on his equity.

Since the problem concerns a large-scale development that offers unusual stability of investment, it is possible that the private developer can obtain capital at 4% and, because the investor will want his capital repaid, the loan might be amortized at, say, 1.5% annually. With annual interest payments fixed at 4% and amortization at 1.5%, the borrower would repay the entire loan in about thirty-four years.' This setup is similar to recent financing under the FHA mortgage insurance plan.

The private developer also must receive a return on his equity or investment. In these days of low capital earning, one may assume a 6% return to be quite attractive. Inasmuch as the rebuilt community is a large-scale affair, requiring adequate public facilities on modern standards, the city could not afford to supply improvements and services without making some charge for them. Therefore, real estate taxes should be included in considering private costs. These private costs may be expressed as:

Item	Percentage of total capital cost
Interest	4% on 80%, or 3.2%
Amortization	1.5% on 80%, or 1.2%
Equity earning	6.0% on 20%, or 1.2%
Taxes	2.75% on 92%, or 2.53%
Total	8.13%

The private developer receives on the average only $370 per dwelling unit to cover these changes. This amount capitalized at 8.13% is $4,550, which represents the total private investment per dwelling unit that can be made economically in this particular case. In a large-scale operation it may be possible to effect such economies that existing structures on the site could be demolished and the new dwellings erected at an average cost of $3,640 per family unit. For this "average" case this development cost is roughly 40¢ per cu ft. At such a favorable rate for construction costs the private developer could afford to pay $910 per dwelling unit for land. If the community is built to house 250 persons per residential acre, land could not cost more than $1.42 per sq ft; at a density of 430 persons per residential acre, the developer could pay $2.45 per sq ft for land. At a density of 540 (provided in rebuilt Unit A_2 of the cost study), the economic value of land is slightly more than $3 per sq ft under these assumptions.

There is not much land in urban slum districts that can be purchased at these figures. At rentals below the afore-stated $520 average, the situation is obviously more difficult, and, inversely, building for rentals greater than $520 is relatively easier. (This average rental does not include rents from stores, parking garages that could be located in the basements of residential structures, nor other miscellaneous income.) Of course, a higher average income might permit higher rents and greater land values, but the resulting increase in living standards could not be counted upon to reduce building costs.

Public and Private Costs.—The sums used in this illustration of an average condition may or may not be valid in so far as the exact private costs of development are concerned. One of the objectives in urban redevelopment is to rehouse people at rents they can afford to pay. With an average rental income of $520 per yr, the private developer can spend only $4,550 per dwelling unit, or approximately $1,240 per person, under the conditions assumed. If the capital charges and operating expenses are larger than those assumed, the total private capital cost would be reduced. The point the writer wishes to make, however, is that, whatever the exact figure, private costs per dwelling unit or per person, based on a given rental income, remain at the same average amount regardless of any change in population density. On the other hand, the cost study shows that public improvement costs per person vary with the density of population. Consequently, a combination of public and private capital costs does not appear to throw as much light on the problem as Mr. McCrosky anticipated.

Mr. Baker emphasizes these economic difficulties in his discussion and asks if it would not be a sound investment to subsidize such residential projects, at least to the extent of overcoming the burden of high land acquisition costs. If it were possible to exempt the project from real estate taxes, the situation could be eased. On the basis of the foregoing illustration, the private developer could spend a total of $6,600 per dwelling unit if he did not have to pay taxes ($370 capitalized at 5.6%). Allowing the same figure for construction ($3,640 per dwelling unit), he could afford to pay about $3 per sq ft for land at a density of 250 persons per residential acre; about $5.25 per sq ft for land at a density of 430 persons per residential acre; and about $6.60 per sq ft for land at a density of 540 persons per residential acre.

What Are the Possibilities?—Large-scale tax exemption would make it nearly impossible for most cities to remain solvent under current means of raising municipal revenue. Apparently, engineers must look elsewhere for a solution. It may be possible to devise ways of reducing private operating and maintenance expenses, and to cut building costs with mass construction methods; or the cost of capital may also be cut in proportion to the elimination of risk in investment. If all of these economies could be made, the high cost of land would still remain an obstacle to urban rebuilding.

Limited tax exemption would be helpful, but it is well known that revenue received from taxes levied on residential property does not cover the actual cost of public services provided in residential sections. For example, total annual expenses for public services in old Area A are estimated at more than $1,600,000 and the tax yield at some $630,000 per yr. If partial exemption, on the basis heretofore mentioned, were granted to the rebuilt Unit A_2, a tax yield of about $820,000 could be expected; but annual expenses for public services would exceed $1,300,000 per yr. Thus, the city would forego a higher tax return, not for the purpose of reducing rents nor to give greater service for the same rents, but to underwrite site costs that are greater than the actual and potential use value of the land.

Perhaps the creation of public land corporations or authorities, with the power of eminent domain and of issuing bonds secured by the land, should be considered. If the land and improvements were subject to real estate taxes, the city's taxing and debt incurring power would not be impaired. This is not an original suggestion (see the FHA *Handbook on Urban Redevelopment for Cities in the United States*). With this type of public ownership, the land could be leased for appropriate private development, and the purchase price of the land could be amortized over a sufficiently long period so that the ground rent charged the private developer would coincide with the economic use value of the land.

Even if land "costs" can be reduced in this manner, the engineer must still find the means to effect economies in construction costs and operating expenses, as well as in charges for the use of capital. Otherwise, large-scale urban redevelopment cannot be attained at economic rental levels. If these or similar devices can be developed and put into operation in the near future, engineers can also perfect their procedures and techniques, and commence the planning and timing of urban redevelopment as an integrated part of postwar activity.

EXTENSOMETER STRESS MEASUREMENTS, NORTH AVENUE BRIDGE, CHICAGO, ILL.

BY LAWRENCE T. SMITH,[1] M. AM. SOC. C. E., AND
PAUL LILLARD,[2] ESQ.

WITH DISCUSSION BY MESSRS. ARTHUR R. LORD, J. CHARLES RATHBUN, AND THEODORE BELZNER.

SYNOPSIS

The design of the North Avenue Bridge (Chicago, Ill.) presented several major structural engineering problems. In developing a rigid-frame design, certain very critical structural assumptions were made which were believed to be quite valid but which lacked definite quantitative substantiating evidence. The importance of the structure justified a systematic extensometer investigation into the actual field-stress condition and structural behavior of the bridge in order to establish the relative validity of these basic assumptions.

As a result of this investigation, the true functional capabilities of this bridge are now known, definitely and accurately, free from the shadow of doubt that often clouds the reflections of the structural designer in his application of pure mathematical logic to the complex factors affecting the higher type of structure.

FIELD MEASUREMENT OF STRESSES

The first recorded instance of the actual field measurement of stress in an existing structure by means of the extensometer was in 1883 when J. J. Frankel described his investigations (12)[3] upon the primary stresses in a Pratt truss bridge. In 1899 M. Mesnager published (27) an account of extensometer stress measurements made upon a railroad bridge. In 1901 M. Rabut described (34) stress measurements on girder and truss railroad bridges. In 1907 the American Railway Engineering Association (A.R.E.A.) conducted stress measurements of limited scope on girder and truss spans to determine relative impact allowances for design purposes (21).

NOTE.—Published in May, 1941, *Proceedings*.

[2] Structural Designer, Bridge Div., Cook Co. Highway Dept., Chicago, Ill.

[3] Numerals in parentheses, thus: (12), refer to corresponding items in the Bibliography (Appendix).

In all of these investigations, which constitute probably the entire scope of the work done in this field until about 1917, no stress measurements were made to compare computed and measured stress or to determine dead-load stress; and no measurements were made on statically indeterminate structures. Such work as had been done was greatly restricted to the determination of live-load stresses and to the evaluation of relative impact. Many of the results contained serious instrumental errors. The use of the extensometer in the systematic investigation of true field stress and the verification of structural design theory applied to an existing structure were of no consequence until 1917 when D. B. Steinman, M. Am. Soc. C. E., conducted his extensive systematic stress measurements on the Hell Gate Bridge (39). This work was done on a monumental scale and remains today probably the most comprehensive stress survey ever made upon a bridge in service.

In the interval from 1917 to date (1941) there has developed an increasing interest in the extensometer as a precision instrument of value to the structural engineer; but the period has been characterized by few stress measurements on structures under construction or in service. The use of the instrument has been confined mainly to investigations upon small models; upon structures erected for specific test purposes, and subject to structural control; and upon structures or members observed under laboratory conditions. In view of the means at hand it is remarkable that the phenomenal progress made in structural design theory in the two decades 1920–1940 has not been accompanied by a wider utilization of the extensometer by structural engineers.

Field stress measurements are expensive, and they are time-consuming and laborious. They require a high order of instrumental and technical skill in order to be of value. Few organizations have the personnel equipped for this work and few can afford the heavy financial outlay for the apparently intangible results achieved. However, there are undoubtedly many situations that arise in practice where the use of this valuable tool would result in a great economy of effort and easily would secure for the engineer the answer to many otherwise impossible stress problems.

Description of Bridge

The Project.—The North Avenue grade-separation project of the Chicago Park District was initiated to provide adequate pedestrian and vehicular grade-separation and traffic-interchange facilities for the introduction of vehicular traffic from the improved LaSalle Street into the Outer Drive of the Chicago Park District, in the southern area of Lincoln Park (see Fig. 1). The project required a complete redesign and reconstruction of most existing facilities over a large area of the park, involving landscaping and the relocation of roadways and walks, sewers and electric lines, and the construction of several large pedestrian subways and a large, skewed, rigid-frame type of vehicular bridge constituting the main unit of the project.

This bridge is designed to accommodate the extremely heavy Outer Drive traffic passing over the likewise heavy northbound LaSalle Street flow. Both streams are interchanged at a junction immediately north of the bridge. Because of space limitations, it was necessary to cross the two streams at a sharp

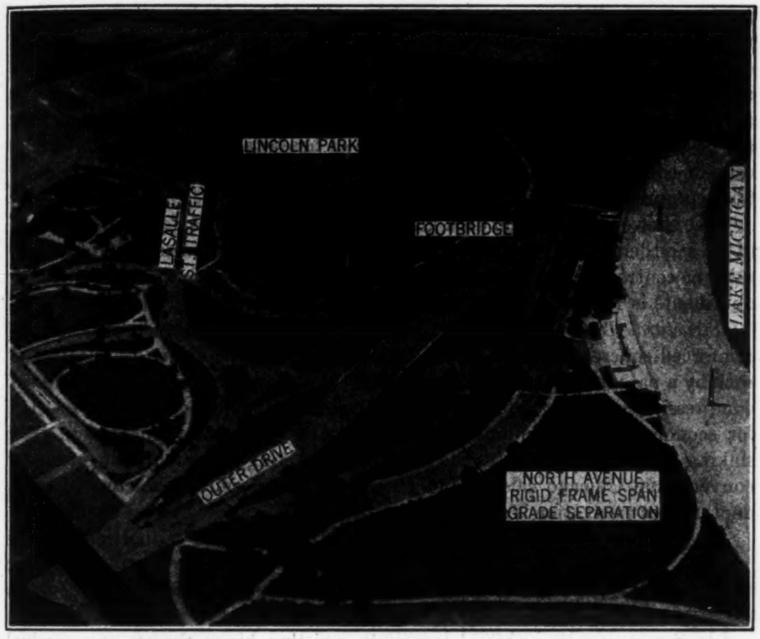

FIG. 1.—MODEL SHOWING LAYOUT OF PROJECT

skew. A high water table prevented an adequate depression of the lower roadway, and the resultant gradient problem placed a definite limitation upon the allowable deck thickness, indicating the use of a structure of the rigid-frame type.

The North Avenue Rigid-Frame Bridge.—The immediate surface stratum at the site consists of a fine lake sand of variable thickness resting upon several strata of glacial till composed of blue-brown clay. Core borings taken at the site showed the upper stratum of this till to be a very wet, soft, plastic, colloidal clay apparently unreliable for major foundation purposes. Load tests made upon this clay showed it to be of little value in supporting a rigid-frame structure. Mantle rock, a reliable Niagara dolomitic limestone of great depth, lies at about 90 ft below Chicago Datum at the bridge site. After considerable study, in which the use of piling was considered, it was decided to rest the structure on cylindrical concrete subpiers driven to mantle rock or to the cemented gravelly claypan which lies immediately above rock. Studies having indicated the existence of much heavier hinge thrusts than could be resisted alone by these subpiers, the lower roadway slab was reinforced and designed to function as a tie in restraining the abutment hinges.

The superstructure is a skewed, two-hinged, reinforced-concrete, rigid frame with deck and abutments of slab-and-girder design and with hinges tied by the reinforcement of the lower roadway slab. The bridge loads are transmitted to rock through spirally reinforced concrete subpiers. The deck is made of slab-and-girder design primarily for economy, but also because of the practical impossibility of predicting stresses in a skewed, rigid-frame bridge of the slab or barrel type. The deck at the crown is of conventional T-beam construction; at the haunches, because of the existence of heavy negative moments, it is of cellular construction with a lower flange slab for the resistance of the bottom fiber compressive stresses.

The skew angle between deck girders and abutments is 55°. The clear span of deck girders is 101 ft and the centroidal span of the frames is 105 ft. The ratio of centroidal rise to centroidal span is 1 : 7. The width of bridge along abutments is 130 ft, and the curb width of the upper roadway is 102 ft.

Structural Design and Stress Analysis.—Supporting subpiers are spirally reinforced-concrete columns of the Chicago caisson type driven to hardpan or rock by a patented rotary process. These subpiers were designed only for axial compression as short reinforced-concrete columns, the diameters being selected for economy and a minimum inspection space. The rotary process used in sinking these piers eliminates the usual large working space requirement of the conventional Chicago caisson and allows the use of small diameters to great depths since excavation is almost completely mechanized. Lateral bending was not provided for in proportioning these subpiers beyond that available in the axially designed section. The tie-slab (Fig. 2) was considered the active agent in resisting hinge thrust, any residual bending being taken by the passive resistance of the substrata. On this basis the tie slab was proportioned to accommodate the entire hinge thrust, unrelieved by active or passive backfill pressures and subpier restraint. In making the design it was not believed that the effect of active or passive backfill forces would be large, either upon hinge thrusts or upon the stress functions of the superstructure. Sleeves for mud-jacking were provided in the tie-slab for the readjustment of the slab in the event of subsequent deleterious settlement.

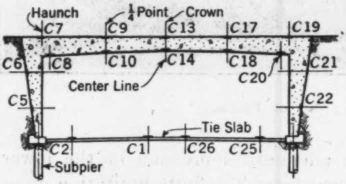

FIG. 2 .—TYPICAL SECTION, SHOWING LOCATION OF STATIONS ALONG CENTER GIRDER

The bridge was designed to carry the Park District standard truck live load, consisting of a file of two 24-ton trucks surrounded by a uniform load of 100 lb per sq ft of deck. Impact was taken at 22%. The maximum temperature differential between superstructure and tie-slab was taken at 25° F, and the effect of hydration shrinkage was based upon a coefficient of 0.0002. No beneficial effect was considered to be derived from active or passive backfill pressures.

Preliminary proportioning was made by means of the moment-distribution method (7), assuming a two-hinged frame of variable moment of inertia. Final analysis of this preliminary proportioned structure, after complete structural detailing, was made by means of the elastic theory, using two separate methods of attack by two computers: (1) Constant $\frac{ds}{I}$, and (2) constant ds. Each analysis was thorough, and the use of the two methods furnished an excellent check. Completion of the analysis by elastic theory showed a very close agreement with the preliminary functions obtained by the moment-distribution method. The bridge was treated for analysis as a series of interior girders or frames, and fascia girders or frames. Each was analyzed separately. As actually analyzed, the frame was assumed to be indeterminate only in the first degree, since the only decisive unknown is the horizontal component of the hinge thrust. The effect of subpier restraint and backfill effort was considered negligible in influencing the hinge thrust and superstructure functions to any significant degree. The horizontal component of the hinge thrust is a function of the properties and loads of the superstructure and the deformations occurring in the tie slab. The equation for hinge thrust under a vertical loading upon the deck is

$$H_0 = \frac{\int_L^R \frac{M'\,y\,ds}{I}}{\int_L^R \frac{y^2\,ds}{I} + \frac{L}{A_s}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which $\frac{L}{A_s}$ represents the restraint of the tie slab. Design studies showed that, theoretically, the effect of the tie slab upon the computed stress functions of the deck is practically negligible, and that small horizontal movements in the hinges produce negligible moment variations in the superstructure. The truth of this statement, in practice, has been established definitely by the results of the extensometer stress study. As measurements during the test showed that there was no movement of the hinges due to applied loads, no elongation of the tie rods was taken into account in evaluating the results. However, the actual design proportioning of the frames was based upon consideration of the tie-slab restraint.

Early stress studies showed the negative moment compression at the haunches to be very high, necessitating the use of a lower flange slab for inverted T-beam action and resulting in the cellular construction of the deck from quarter point to abutment. This cellular part (Fig. 3) was detailed with a taper in the lower flange slab starting at the quarter point and widening out to full width at the abutment. As finally treated, it produced a very satisfactory architectural motif strongly suggestive of greater span and strength.

Shears in the deck girders are high and are accommodated by bent bars and by vertical stirrups. For the accommodation of leg shears, which (according to recent laboratory investigations) are uncertain in actual intensity and are probably much higher than the computed values, more shear reinforcement was used than was indicated by conventional theory.

The abutment hinges were detailed to allow a fairly free rotation with a minimum of moment transmission into the subpiers. The subpiers, however, move horizontally in conjunction with the tie-slab and the abutment hinges. The tie-slab is anchored positively to the lower legs and the hinges. A heavy subpier cap girder was provided to effect a lateral distribution of unequal local loads to the subpiers, and a like provision was made for the distribution of local loads to the lower part of the abutment legs by the thrust girder.

The effect of skew was neglected in analyzing and proportioning the interior frames, although it is obviously a factor in the action of the fascia and adjacent outer girders under certain asymmetrical loadings. However, it was deemed satisfactory to proportion the frames by conventional methods. The wisdom of this course has since been proved by the results of the stress measurements made upon the completed structure.

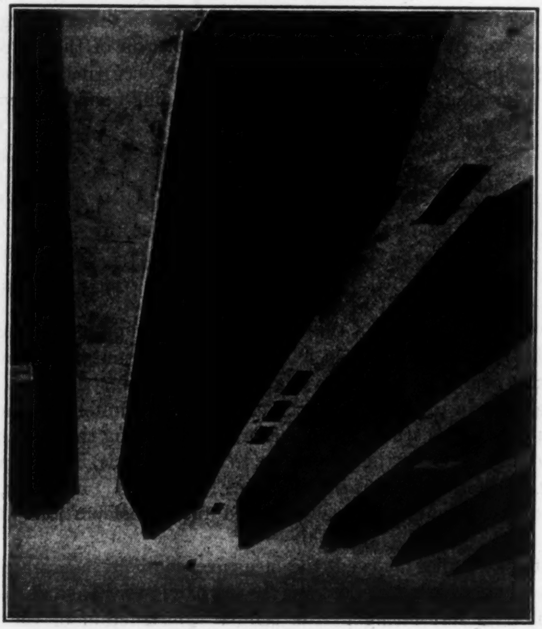

FIG. 3.—MAIN-FRAME DECK GIRDERS BEFORE CEMENT FINISHING, SHOWING CELLULAR HAUNCHES AND EXTENSOMETER STATIONS

The total weight of reinforcing steel used in the superstructure (Fig. 4) and tie slab was 374 tons, and the total volume of concrete was 2,650 cu yd, a volumetric proportion of 2.1%. The setting of steel presents a difficult problem because of the weights and lengths involved. However, this percentage of steel (2.1%) is very reasonable, compares very favorably with that of other structures, and indicates economy in the use of this type of bridge.

Construction.—In sinking the subpiers it was necessary to develop a technique especially adapted to the peculiar subsurface conditions and the rotary process used. A primary requirement in building a structure of this type is the proper design of an unyielding centering and its skilful erection. In this kind of structure, in which few lines are straight, a high quality of workmanship on the part of the carpenter is of vital importance.

Although the structure was built with Park District forces, a close field engineering control was established very early for purposes of securing a uniform production of concrete, satisfactory control-test cylinders for use in the stress measurements, and a qualified inspection service during the construction period.

Control-test cylinders were made from each pour and were subjected to breaking tests to establish the quality of the concrete. A number of these cylinders were given stress-deformation tests to secure the stress-deformation

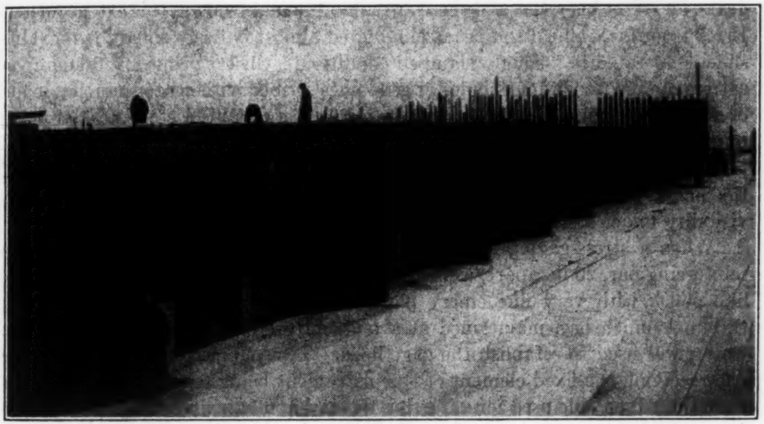

FIG. 4.—VIEW SHOWING REINFORCEMENT AT THE HAUNCH

diagram below the failure point. This was likewise done for specimens of reinforcement cut from the bridge. The results were used in selecting the value of $n = \frac{E_s}{E_c}$, which was taken as 10.

EXTENSOMETER STRESS MEASUREMENTS

Object.—The massive character and the importance of the structure were two of the several reasons why it was considered advantageous to conduct an extensive series of strain-gage extensometer measurements: (1) To ascertain the true stress condition as a matter of safety, (2) to make a comparison of true and theoretical stresses as a matter of structural engineering research, (3) to study the elastic action of the system and the behavior of the bridge under service conditions, and (4) to secure data of value in the future design of similar bridges.

Preparation of Stress-Gaging Stations.—For the measurement of stresses twenty-eight strain-gage stations were provided for in the design and were built into the deck girders, tie-slab and abutment legs of the center-line interior frame, and the east fascia frame (see Fig. 3). At each station the outer face of a length of reinforcing bar carrying computed stress was formed, partly exposed for observation; a thermometer pipe was embedded to the center of the concrete mass; and a pair of thermocouple leads were embedded for the potentiometer determination of internal concrete temperature.

An extensometer designed especially for this study (see Fig. 5) was used most of the time. The instrument consists of a channeled brass bar in which two snugly fitted brass slides move, each holding a sharply pointed center punch. The one slide is clamped securely in position and remains fixed during any given series of measurements. The other slide, being adjustable and actuated by a knurled nut and threaded shaft, is the movable element of the instrument; and its extreme end bears against, and actuates, a strain-gage dial. There are no gears, levers, or bearings, and there are a minimum of parts in this extensometer. Error from mechanical sources is eliminated almost entirely since the movable slide is operated in a snugly clamped condition. Observations are taken upon extremely fine punch-mark holes or gage lines scribed with center punches made of hard alloy drill steel rigidly attached, 20 in. apart, to a steel standardizing punch bar or trammel. The gage points or lines are scribed upon highly polished areas of the reinforcing bar; they are made by a very light pressure of the hand, producing a line as small and as fine as possible consistent with visibility under a strong magnifying glass.

When a stress-gaging station was originally established, two areas of the reinforcing bar, 20 in. apart, were ground smooth and given a very high mirror-like polish with very fine emery paper and jewelers' rouge. The standard, trammel punch bar, maintained at a temperature of 32° by immersion in ice water, was used to establish the gage lines. Two punch holes were made, the one receiving the fixed element of the instrument being made somewhat larger than the punch hole used for adjusting the dial in making readings. The latter hole was made extremely small, and its use was primarily as a reference point, although accurate observations could be made upon it. Actual readings were taken upon the extremely fine gage lines scratched across the polished face of the steel reinforcement.

Stress measurements were made by a team of two structural engineer observers assisted by two or three nontechnical helpers who prepared stations, held flashlights, and carried on the skilled mechanical work required in cutting bars, arc welding, polishing, grinding, building scaffolding, and handling test loadings. These helpers were usually skilled carpenters or ironworkers. In Fig. 5, the strain-gage dial, the reading end of the instrument, and the gage line being observed are at the observer's right hand. The alternate observer is holding the fixed point in its position. The standard punch bar for scribing lines rests on the tool box.

Instrumental work of this nature, conducted under widely varying temperature conditions, requires a base for length comparison that is practically unchangeable under ordinary temperature variations. For this purpose a square, forged bar was used, which was made of a high nickel-iron alloy with a coefficient of temperature expansion of 0.0000004 to 0.0000005, which is about one sixteenth that of structural bridge steel. One face of this bar was brought to a mirror-like polish. Gage points and lines were established on this polished face for each series of stress measurements. This was done with the reference bar and the trammel punch bar maintained at 32°. The function of these gage lines on the reference bar was to provide a base of unchangeable length to which the extensometer could be applied in each reading and given its initial zero setting. By application of the extensometer to similar lines established on the reinforcing bar under observation, a direct comparison of length is made and the true difference or deformation is indicated on the gage dial. For record and identification each set of gage lines was circled with colored paint, different colors being used for the various loadings and stress series. The reference bar, as well as the standard trammel punch bar, was kept in ice water throughout any series of stress measurements. It was found that, with a little care, the temperature changes in the brass extensometer bar could be minimized. As a matter of fact, the short time that ordinarily elapsed between index reading and index check reading upon the reference bar furnished an excellent check on any temperature errors originating in the extensometer. The use of the thermocouple installation was found to be time-consuming, and the main reliance was placed upon the use of a large number of accurate mercury thermometers. All stress readings were corrected for temperature variation by reduction to a common station temperature, assuming a free adjustment of the reinforcing to thermal change without the development of temperature stress. This is not

FIG. 5.—MAKING STRAIN-GAGE MEASUREMENTS WITH SPECIAL EXTENSOMETER

strictly true, however, and does not entirely eliminate the temperature factor from measured stresses since the corrected deformations contain a temperature increment that it is quite impracticable to evaluate. This increment for temperature varies to a maximum of about 15° and is very small and negligible in amount, so that assuming it to be zero produces deformation readings within a very satisfactory range.

Scope of Extensometer Stress Measurements.—Extensometer stress measurements were made upon the structure under the following conditions of loading:

Load	Description
Dead Load	Structure under its own dead load, backfill pressures, and restraint from subpiers.
Test Live Load I	A transverse test load of 65 tons uniformly distributed along the crown of the bridge on the skew parallel to abutments, producing a concentrated load of 6.6 tons at the crown of each deck girder.
Test Live Load II	A transverse test load of 105 tons uniformly distributed along the crown of the bridge on the skew parallel to abutments, producing a concentrated load of 8.1 tons at the crown of each deck girder.
Test Live Load III	A longitudinal test load of 79 tons placed directly on the center-line interior girder and uniformly distributed to simulate the conventional truck live load used in design.
Test Live Load IV	A transverse test load of 160 tons uniformly distributed along the crown of the bridge on the skew parallel to abutments, producing a concentrated load of 13.8 tons at the crown of each deck girder.

BEHAVIOR OF STRUCTURE AFTER REMOVAL OF CENTERING AND UNDER TEMPERATURE CHANGES

Temperature Changes in the Structure.—A systematic record was made of hinge movements, deck deflections, and temperature changes in air and bridge concrete during the period of the investigation. The results of these observations furnish an interesting portrayal of elastic condition and present much valuable evidence for certain conclusions concerning the actual physical behavior of the structure.

Temperature observations on air and concrete were made in great detail over a period of about four months, embracing a mean high concrete temperature of 78° and a mean low concrete temperature of 16°, a mean high air temperature of 96° and a mean low air temperature of 15° below zero. When extensometer observations were actively under way, periodic readings were taken at all stress-gaging stations repeatedly during the day in order to furnish a reliable basis for the temperature adjustment of stress measurements.

The result of the observations on air and concrete temperatures is plotted as shown in Fig. 6. No attempt has been made to smooth the curves. The points as plotted in Fig. 6(*a*) represent the mean temperature observed during daylight hours. No temperature observations were made at night so that the physical effect of nocturnal changes is not shown in the temperature curves. Because of this fact, and because the value plotted is actually the daily mean temperature, the lag of concrete temperature behind air temperature is not clearly shown in some instances.

An examination of the air and concrete temperature curves shows the very quick response of the structure to air-temperature changes. This response is very much quicker than is customarily assumed. With air temperatures ranging from plus 32° to plus 95°, the largest observed difference between concrete and air was only 20° and only for a short period of time (six hours). Except for occasions of sudden change, the temperature of the bridge concrete follows very closely that of the adjacent air. Subsidiary local effects were observed—the greater warming of fasciæ under summer sunlight, their greater cooling under strong lake gales, and the quicker response of crown and the slower response of abutments. The mean temperature of the tie-slab coincided closely with that of the superstructure, the greatest daily difference being only 3°. With air temperatures below the freezing point and as low as 15° below zero, however, the thermal effect of the heat retained in the larger backfill mass produced a response in the bridge different from that observed for air temperatures above the freezing point. Thus, when the air temperature dropped to 15° below zero and continued at that low level for two days, remaining below

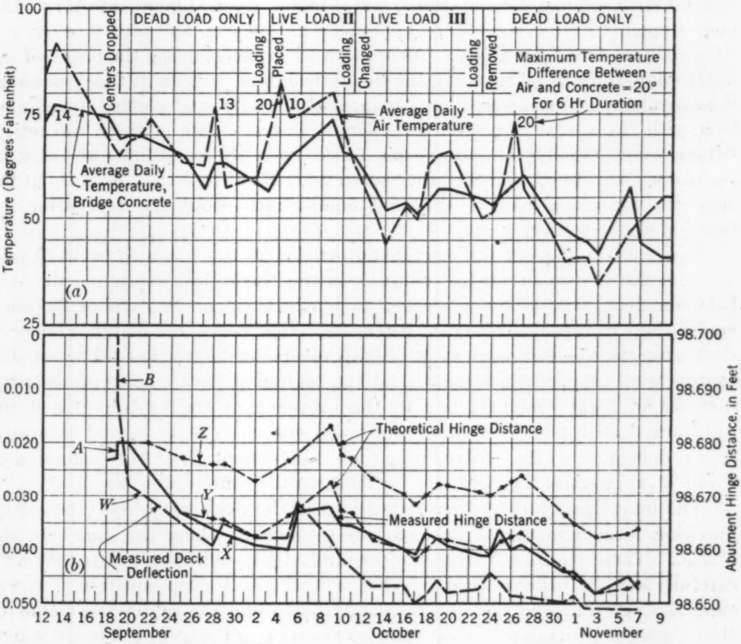

FIG. 6.—DAILY TEMPERATURE VARIATION, MOVEMENT OF HINGES, AND DEFLECTION OF DECK

10° below zero for about seven days, the temperature of the deck dropped only to 15° above zero and remained at that level throughout the low period until the air temperature had risen to above freezing. This action is to be expected because of the slow penetration of frost into the backfill mass. Until this soil is generally frozen, there will be a definite heat transfer from the relatively warm backfill to abutment legs and deck, resulting in the dampening action that is observed in the structure in sub-freezing temperatures.

Hinge Movements and Deck Deflections.—The investigation of the hinge movements was based primarily upon daily precision measurements of the longitudinal horizontal distance between the abutment hinges of the center-line interior frame. No observations were made upon hinge rotations. All measurements were corrected for temperature, tape sag, and tape tension, and were reduced to 32° for study. As an adjunct in ascertaining the origin of the day-to-day hinge displacements, the theoretical hinge lengths of the deck under the same temperatures were computed, reduced to 32°, and plotted in conjunction with the actual measured hinge-length curve. Two of these theoretical curves were actually computed—one based upon the conditions at the time centers were dropped, and the other based upon conditions that obtained at the time the structure reached apparent equilibrium about six days after the removal of the centering.

In Fig. 6(*b*): Curve *X* is the actual adjusted measured distance between gage lines on the abutment hinges; curve *Y* is the theoretical computed distance between deck gage points corrected to temperature on September 25 when equilibrium was reached; curve *Z* is the theoretical computed distance between deck gage points corrected to the temperature on September 19, when the centers were dropped (increment *A* at the beginning of curve *Z* represents the increase in hinge distance, due to the dropping of the centering, and the resultant dead load on the structure); and curve *W* is the actual measured crown deflection of the center-line girder. Increment *B*, at the beginning of curve *W*, represents the deflection at the time the centers were dropped.

The investigation of vertical deflections in the deck was based upon daily precision measurements at five stations established along the crown of the bridge. These stations consisted of carefully built deflection gages that were carefully scribed prior to dropping the centering. A deep concrete post was sunk through a hole in the tie-slab at midspan under the center-line frame for the purpose of providing precision points for checking the results of observations on the deflection gages. A brass plug in the girder overhead and a similar plug in the independently founded post provided these precision points. These deflection observations were likewise reduced to 32° for study.

Readjustment Period Following Removal of Centers.—A study of the curves of observed hinge distance, observed deck deflection, and observed temperature variations indicates the existence of a distinct period of structural readjustment of about six days duration following the removal of the deck centering before the structure reached equilibrium under its own dead load.

At the time centers were struck, this heavy timber framework supporting the deck had been in place eighty-one days under the full load of the deck. It transmitted this load, in turn, to the tie slab upon which it rested. The superstructure, tie slab, and subsoil supporting the tie slab had been in equilibrium under this load condition for many weeks. Striking the deck centering removed the heavy vertical loads which had rested upon the tie slab and which had produced a compression in the subsoil. This subsoil is of poor structural character. Bearing tests made prior to design showed it to be very plastic and low in restoration properties. It is probable that the arched crown of the tie slab facilitated the development of appreciable outward thrusts upon the abutment hinges under the action induced by the plastic condition of the subsoil under the centering load. These thrusts apparently caused an outward movement of the hinges prior to striking of the deck centers, and the system had stabilized in this condition.

Striking of the deck centers removed the heavy centering load from the tie slab, but the plastic nature of the subsoil precluded anything other than a slow recovery of subsoil and tie slab to the unloaded condition. The tie slab recovered slowly, attaining its dead-load equilibrium only after about six days of movement. During this period the hinges drew inwardly at a much greater rate than was indicated theoretically by temperature change. After equilibrium was reached, the horizontal movements in the hinges were almost entirely of temperature origin and were caused by variations in the length of the bridge deck under changes in temperature. The observed day-to-day movements in the hinges are in very close agreement with the theoretical values computed for temperature changes only.

Conclusions Concerning the Behavior of the Bridge.—The following conclusions seem warranted as a result of the study made upon the behavior of the bridge under temperature change and at the striking of centers:

(1) There was a definite readjustment period of about six days, which followed the removal of the deck centering, before the structure attained static equilibrium. During this period the hinges moved inwardly at a greater rate than theoretically computed for the temperatures observed during the period. This phenomenon is traceable to the retarded recovery of the subsoil supporting the tie slab, following the removal of the deck centering load which it formerly sustained. When final equilibrium was reached, at the end of this readjustment period of six days, the structure behaved elastically and geometrically as predicted by theory.

(2) After structural equilibrium is reached following the period of readjustment, the abutment hinges move horizontally in very close response to temperature changes in the superstructure. There is a very close agreement in the curves of theoretical and observed hinge distance, indicating that nearly all of this movement originates in length changes in the deck under temperature variations.

(3) After structural equilibrium is reached, the effect of the restraint of the subpiers and the passive resistance of the approach backfill is apparently quite negligible in modifying the action of the hinges.

(4) The very close agreement of the curves for theoretical and measured hinge distance indicates a probable low magnitude for temperature stresses in the structure. This is further established by the results of the extensometer measurements.

(5) Above the freezing point the internal temperatures of the bridge concrete respond very quickly to variations in air temperature. Below the freezing point the retained heat in the unfrozen backfill soil mass exerts a distinct dampening action on changes in temperature in the superstructure, retarding very greatly the response of concrete temperatures to sub-freezing air temperatures.

Comparative Study of Stress Measurements

Extensometer Measurements Under Dead Load.—The design provided for a crown key to reduce the accumulated shrinkage stresses. This key was poured thirty days after the first deck pour was made. Abutment backfilling started several weeks later, and upon its completion the deck centering was struck—eighty-one days after the pouring of the crown key. The behavior of the deck centering at the time it was struck, the circumstances under which the dead-load stresses were measured, and the close agreement of dead-load stresses measured by standard extensometer procedure and by the cut-bar technique indicated strongly that the centering was still carrying a very considerable part of the weight of the deck.

The measured and theoretical computed stresses under dead load show surprisingly close agreement. For purposes of comparison between measured and theoretical conditions, the measured stresses were used in computing equivalent resisting moments. Compression stress readings in most instances ran excessively high, a condition directly traceable to flexure in the station reinforcing bar in the exposed length that was partly or entirely freed of bonding concrete. The results given in this paper are based accordingly upon the observed tensile stress in the steel and the theoretical linear location of the centroidal axis, assuming no concrete in tension. There is a strong probability of the concrete taking tensile stress, which might tend to modify the measured moments; but it was deemed more practicable to assume the tensile-free condition commonly used in design. The standard linear flexure equation for compression-reinforced T-beams was used in deriving the equivalent measured moment from the measured stress. The moment of inertia of transformed sections was used. The use of a parabolic flexure equation in computing measured resisting moments was given some study but was not deemed practicable.

In order to determine the total combined stress from dead load, temperature change, hydration shrinkage, backfill effort, and subpier restraint (which existed in combination after striking of the deck centering), and to secure a check upon the dead-load stresses that were measured at the time the centering was struck, stress measurements were made upon a number of bars, using the cut-bar technique which the writers developed to facilitate the solution of this special problem. This cut-bar technique involved:

(*a*) Careful removal of the concrete cover from a reinforcing bar carrying computed stress;

(*b*) Preparation of gage lines on the reinforcing bar and on the reference bar;

(*c*) Readings for index reading before any further bonding concrete is removed;

(*d*) Careful removal by hand chipping of all bonding concrete between gage lines;

(*e*) Intermediate reading for deformation;

(*f*) Careful cutting of the bar outside the gage length in a manner causing no temperature changes in the bar;

(*g*) Final reading for deformation in the no-stress condition; and

(*h*) Arc-welding the severed ends of the bar to restore some part of the structural value.

Stress measurement with the cut-bar technique was done in such a manner as to show the true, total, unmodified stress of all origins existing in the bar at the time of measurement. Stresses measured by this technique are entirely free from the error due to imperfect temperature corrections. The series of measurements made by this method furnished an excellent check on the measurements made by the standard dead-load procedure. It is believed that the cut-bar technique is essentially a new departure and certain to be of value in future studies involving extensometer stress measurements.

A study of the data secured in the stress measurements upon the center-line interior frame is summarized in Table 1. The significance of the various column headings in this table may be clarified further, as follows:

Col. No.	Description
2	Extreme temperature range at the station during stress observations
3	Arithmetical mean of observed dead-load deformations at the station, corrected for temperature
	Stress in the Steel Reinforcement, Computed by Means of:
4	Young's modulus
5	Elastic theory
	Bending Moments at the Station:
6	Theoretical
7	Measured resisting moment, computed from the measured tensile stress and an assumed centroid

A graphical comparison of computed and measured stresses and moments is shown in Figs. 7 and 8. On these curves:

C denotes computed theoretical stress or bending moment for the loading indicated;

M denotes the measured stress (Fig. 7) secured by means of a standard extensometer, or the equivalent measured resisting moment (Fig. 8), using the measured tensile stress and a theoretical centroid; and

MS denotes the measured combined stress (Fig. 7) secured by the cut-bar technique, or the equivalent measured resisting moment (Fig. 8), using the tensile stress and theoretical centroid in the cut-bar technique.

(*a*) DEAD LOAD

(*b*) TEST LIVE LOAD III

(*c*) TEST LIVE LOAD IV

FIG. 8.—COMPARISON OF THEORETICAL AND MEASURED MOMENTS (INTERIOR FRAME)

Stations C 7 and C 19 were at the face of the abutment; Station C 14 was at the midpoint of the frame; and stations C 9 and C 17 were at the quarter points. No readings were taken at stations C 9 and C 17 during test live loads III and IV.

The following conclusions seem warranted by the data secured in the measurements under dead load (see Figs. 7(*a*) and 8(*a*)):

(6) Under dead load the structure is stressed very close to the theoretical values computed by means of elastic theory.

(7) The basic design assumptions (a two-hinged tied frame with hinges restrained by the tie slab against horizontal movement, but free to rotate, and a sufficient flexibility in the subpiers to warrant the neglect of their restraining action) were correct.

(8) The very close agreement between stresses measured by the cut-bar technique, those measured by the usual extensometer procedure, and those computed theoretically (obtained under widely varying temperatures) leads to the conclusion that temperature stresses, shrinkage stresses, and stresses originating in backfill effort and subpier restraint are quite small. Conclusion (8) is further indicated by the observed action of the abutment hinges under temperature change.

Under dead load the fascia frame is stressed in close agreement with the theoretical. It was not possible to use the cut-bar technique in the measurement of fascia girder stresses, so that no measured value was secured of the stress combination present under dead load; it was also impossible to secure stress-measurement data on an entire fascia frame, since only one half of the east fascia frame was observed. Accordingly, the objection was limited to a determination of stress under dead load by standard procedure, and to a comparison with the theoretical values used in proportioning. Significant quantitative stress-measurement data, from which to make general conclusions concerning the elastic effect of skew, were not secured in this phase of the investigation.

Stress Measurement Under Test Live Load I.—Test Live Load I was a test loading of 65 tons of cement in sacks distributed uniformly and transversely along the crown key on the skew parallel to abutments. This loading produced, effectively, a load concentration of 5.5 tons at the crown or midspan point of each deck girder. Extensometer stress measurements showed the amount of this loading to be insufficient to produce deformations of any significance, and the loading was increased, therefore, to that of Test Live Load II.

Stress Measurements Under Test Live Load II.—Test Live Load II was a test loading of 105 tons of cement in sacks distributed uniformly and transversely along the crown key on the skew parallel to abutments. It produced, effectively, a load concentration of 8.1 tons at the crown or midspan point of each deck girder. By placing this load on the skew, the effect of skew was probably eliminated entirely from the measured stresses of both the interior and the fascia frame.

Extensometer measurements showed that this loading was likewise insufficient in amount to produce deformations of significance, and the loading was therefore increased to that of Test Live Load IV.

Stress Measurements Under Test Live Load III.—Test Live Load III was a test loading of 78.7 tons of cement in sacks placed directly on the center-line interior girder between abutment lines. It very closely simulates the live load of conventional design, composed of two 24-ton trucks surrounded by a uniform live load of 100 lb per sq ft. This test loading was applied in such a manner that the entire weight rested upon the girder proper and no weight rested upon the flange slab. Thus placed, the true lateral distributive value of the flange slab is more easily studied. The characteristics of Test Live Load III are shown in Fig. 9.

FIG. 9.—CHARACTERISTICS OF TEST LIVE LOADS III AND IV

Stress measurements on the interior frame under Test Live Load III are summarized in Table 1(*b*). A graphical comparison of computed and measured stresses and moments is shown in Figs. 7(*b*) and 8(*b*). The following conclusions seem warranted by the data secured in the stress measurements under this load:

(9) The structure functions as an elastic two-hinged tied frame with true measured stress functions very close to those indicated by the elastic theory.

(10) The measured crown moment, which was 71% of the theoretical value, indicates that there is apparently some lateral distribution of the load to the adjacent unloaded deck girders via the deck-slab flange.

(11) The measured haunch moments, which average 50% of the value obtained by conventional assumptions as to load distribution, indicate that

there is evidently an appreciable lateral distribution to the adjacent unloaded deck girders via the deck-slab flange and the cellular haunch slabs.

Stress measurements on the fascia frame under Test Live Load III indicate the existence of what is probably a complex torsional condition resulting from the skew of the structure. The objectives of this investigation did not embrace a study of this phase in the fascia and outer frames. The results secured by the stress measurements on the fascia frame were satisfactory and indicate that the stress under Test Live Load III is within safe limits.

Stress Measurements Under Test Live Load IV.—Test Live Load IV (Table 1(*c*)) was a test loading of 159.7 tons of bank sand retained in a timber crib, distributed uniformly and transversely along the crown key on the skew parallel to abutments. It produced, effectively, a load concentration of 13.8 tons at the crown or midspan point of each deck girder. Stress measurements were limited to the center-line girder only. This loading was 1.7 times heavier than Test Live Load II, and the stress measurements were made under a much smaller temperature range. The magnitude of the temperature corrections applied to the station measurements was considerably smaller in each case and resulted in a much smaller error from this source.

In this series the actual measured stresses were found to be in close agreement with the theoretical; in fact, the average variation was only about 12%. A comparison of the theoretical bending moments and the measured resisting moments, computed from the measured tensile stresses and the theoretical locations of the centroidal axis, indicates that under Test Live Load IV the following conclusions are warranted:

(12) The interior frames are stressed close to the theoretical values computed by means of the elastic theory.

(13) The basic design assumptions (a two-hinged tied frame with hinges restrained by the tie-slab against horizontal movement, but free to rotate, and a sufficient flexibility in the subpiers to warrant the neglect of their restraining action) were correct.

(14) The close agreement of measured and theoretical stress functions indicates that subpier restraint and backfill effort are quite negligible in modifying appreciably the stress condition of the superstructure.

Service Load Test.—It was considered desirable to make a service load test upon the completed bridge for assurance of safety under severe conditions. To effect this, the loading of Test Live Load IV was increased to 180 tons and an additional 60 tons of loaded trucks and tractors were arranged along the crown in midspan, bringing the total loading to 240 tons. To augment this static load, and to impose a still more severe condition, a 15-ton tractor was maneuvered rapidly about the deck in a manner to produce heavy impact shocks. Although this service load did not even begin to approximate the capacity of the structure, it was a severe load and is probably the largest the structure as a whole will ever be called upon to accommodate.

CONCLUSIONS

In addition to those presented in the body of the paper, the following general conclusions are offered:

(15) The basic structural assumptions that were made in the original design analysis and in the detailed proportioning of the components of the bridge were found to be valid and correct. They were well sustained by each phase of the investigation.

(16) The effect of active or passive backfill pressures is negligible in modifying appreciably the stress condition of the superstructure. Likewise negligible is the effect of the restraint developed by the subpiers upon the stress condition of the superstructure.

(17) The interior frames function, structurally, very closely as predicted by the elastic theory. In these frames the effect of skew is apparently very small for skewed symmetrical loadings similar to Test Live Load IV, and it may be neglected in proportioning the components in design. Under Test Live Load III there was a lateral distribution of load to the adjacent unloaded frames via the flange slabs. Under dead load and under Test Live Load IV the interior frames are stressed very closely to the theoretical values.

(18) The fascia frames under dead load function similarly to the interior frames. Under a symmetrical loading they show the effect of skew by a departure from the pattern common to the interior frames. However, proportioning the fascia frames by conventional methods is commensurate with safety.

(19) The assumption made in design that the hinges move freely in response to temperature variations in the superstructure, relatively unimpeded by the backfill and subpier resistance, was found to be valid. This assumption is particularly sustained by the study made of the hinge movements where the day-to-day variation in true hinge distance was found to be caused entirely by changes in length of the deck under temperature variations.

(20) By means of the cut-bar technique, the true, total, unmodified stress of all origins existing in the reinforcing at the time of measurement under the dead-load condition may be determined accurately. Use of this technique furnishes a close check on the measurements of dead-load stress secured by the standard procedure.

ACKNOWLEDGMENT

The original thesis from which this paper was prepared was presented to the Armour Institute of Technology (later part of the Illinois Institute of Technology), in Chicago, in 1940, in partial fulfilment of the requirements for the professional degree of Civil Engineer. The extensometer used was devised by Prof. Phillip C. Huntly of Armour College of Engineering, Illinois Institute of Technology, Chicago. It was made in the Institute shop under Prof. Huntly's direction. The instrument is not patented. In addition to Professor Huntly, the writers wish to acknowledge, especially, the valuable advice given them in this investigation by C. Thomas Kelly, and Edward Smulski.

DISCUSSION

Arthur R. Lord,[4] M. Am. Soc. C. E.—There is a strange lack of information, in this paper, as to the early state of the art of stress measurement. The statement is made under the heading "Field Measurement of Stress" that:

> "In all of these investigations, which constitute probably the entire scope of the work done in this field until about 1917, no stress measurements were made to compare computed and measured stress, or to determine dead-load stress; and no measurements were made on statically indeterminate structures. * * * The use of the extensometer in the systematic investigation of true field stress and the verification of structural design theory applied to an existing structure were of no consequence until 1917 when D. B. Steinman, M. Am. Soc. C. E., conducted his extensive systematic stress measurements on the Hell Gate Bridge."

The Bibliography given in the Appendix shows a serious lack of important references. To correct this inaccurate record it should be stated that:

(1) The first test for actual stresses in a structure was made on the Deere-Webber Building in Minneapolis, Minn., in the fall of 1910 and described by the writer in a paper published that year.[5] This paper involved extensometer measurements in a statically indeterminate structure and comparison of actual with computed stresses, and it laid the foundation for the design of the reinforced concrete flat-slab construction in the United States and other countries.

(2) Many other tests, each involving thousands of extensometer readings under heavy loads in actual service structures, were made in the years between 1910 and 1917, by the writer[6] and by many others, and were published and discussed throughout the United States. The bulletins of the Engineering Experiment Station at the University of Illinois, Urbana, Ill., give the full record of some of these tests. The *Proceedings* of the American Concrete Institute give others. The *Engineering News-Record* contained abstracts of several. In other words, there is a mass of scientific testing, of precisely the type reported by the authors, that preceded the test in 1917. Dead-load stresses were measured, as well as live-load stresses. Stresses (deformations) developing over periods as long as a year, in structures subject to load and temperature effects, were determined. Effects of "plastic flow" of concrete were noted and evaluated. In fact, the entire scientific design base for hundreds of millions of dollars worth of concrete buildings was developed from such tests. The authors may be justly criticized for ignoring this prior record when essaying to write an historical summary such as is presented in the opening paragraphs and in the bibliography of this paper.

[6] "Measurement of Actual Stresses in a Cantilever Flat Slab Reinforced Concrete Floor Having Rectangular Panels," by Arthur R. Lord, *Proceedings*, National Assn. of Cement Users, Vol. IX, 1913, p. 127.

It is sincerely hoped that the authors will correct these shortcomings in their closing discussion. For example, the works[7] of Arthur N. Talbot, Past-President and Hon. M. Am. Soc. C. E., and the late Willis A. Slater, M. Am. Soc. C. E., as well as that of the writer and many others, antedate any references that appear in the paper.

J. Charles Rathbun,[8] M. Am. Soc. C. E.—The title of this paper does not indicate that it is an attempt at verification of one method of analyzing the stresses in a skew arch; nor does the "Synopsis" so indicate. It is only at the bottom of the third page that the most important phase of the paper appears (see heading "Description of Bridge: The North Avenue Rigid-Frame Bridge").

The "Synopsis" of this paper indicates that field tests were made in order to verify certain very critical structural assumptions "which were believed to be quite valid but which lacked definite quantitative substantiating evidence." The writer takes issue with this statement as well as with the second paragraph of the "Synopsis."

The type of design and method used were fully covered from a theoretical standpoint in a paper[9] by the writer published in 1924; and the results of the authors' test could all have been anticipated in terms of that theory. The general case of the skew arch ring was analyzed, as well as the special case considered by the authors. All test loads used by Messrs. Smith and Lillard were included in this special case. Therefore, it seems fair to state that the action of the North Avenue Bridge under a more general loading condition has not been shown experimentally.

Although the authors may have been justified in using it for other reasons, the slab-and-girder type of construction has two objectionable features in the case of this bridge. The deep girders cut down the headroom materially compared to that of a simple barrel arch; and this type of construction increases the difficulty of analysis and the uncertainty of stress conditions materially. The writer knows of no formula for torsional rigidity or stress distribution for a shaft of the cross section given in Fig. 9(*d*). There are several for a simple rectangle of all degrees of side ratio, including the extreme case used in the skew barrel arch and the case of the skewed rib used by the authors.

At the time that the skew arch theory[9] was first published (1924), there was some criticism of it because of the length of the equations involved and because the results were not in accord with the then popular idea of the action of a skew arch. Since the publication of this paper, a number of papers have been written on the subject and many models have been tested until now (1941) it has been definitely substantiated that the theory is sound. The writer conducted a series of tests and published the results in 1930.[10] Later he tested[11] a multiple skew arch designed by an extension of this same theory by the method developed by the late George E. Beggs, M. Am. Soc. C. E. These tests proved the validity of the theory and also the extension of the theory to the case in which there is more than one arch ring. In 1926 the Society's Special Committee on Concrete and Reinforced Concrete Arches took issue[12] with the findings of the first paper.[9] Professor Beggs was instructed to conduct a series of experiments subjecting four skew arches of varying widths to all possible conditions of vertical load. After more than a hundred loadings were investigated, the Committee came to the conclusion that the theory as published is correct and leads to correct results.[13]

[10] "Crown Stresses in a Skew Arch," by J. Charles Rathbun, *loc. cit.*, Vol. 94 (1930), p. 135.

At present the theory is recognized as correct and is being used in design throughout the United States. The writer has not heard of any engineer, who has designed by it, indicating that it is incorrect or leads to incorrect results; or who feels that, when used understandingly, it is too long and involved. The writer, therefore, takes issue with the second sentence and the second paragraph of the "Synopsis" on the ground that quantitative, computable evidence was available, and that no test loads were applied that fell outside the special case in which the authors' assumptions were valid.

It will probably be of interest to compare the elastic theory of the skew arch with the authors' series of tests and their method of design to encourage a better understanding of the skew arch and its analysis. The problem is essentially one of space analysis. If the reaction at a section across the crown or at an abutment is considered, six components of this reaction must be evaluated—forces in the direction of each of the assumed axes and moments about the line of action of these forces. This makes the arch ring statically indeterminate with six redundants.

Six equations of elastic deformation are required to evaluate these unknown moments and forces. If the deformations due to ring shortening and shear, both horizontal and radial, are considered, these equations become quite lengthy. Therefore, the work required to make a complete analysis is prohibitive, and the practicing engineer leaves out the terms that have little effect on the final result. In the case of the symmetrical arch, even when unsymmetrically loaded, these six equations split into two groups—one of four, and the other of two, equations. In the case of certain types of symmetrical loading (those used by the authors), the one group of two equations gives zero results—that is, the vertical shear and the moment about the vertical axis at the crown are zero.

Although it has little bearing on the present problem, consider the case in which the skew is zero. These six equations split still further into two equations of one unknown each and two sets of equations of two unknowns each. If the loading is symmetrical about the center line of the upper roadway (the common case in arch analysis), three equations have zero results and are not considered by designers. The other three consist of two of two unknowns and one of one unknown. This is the case considered in textbooks on arches. If, still further, the load is symmetrical about the crown, one equation (for vertical shear) disappears. The two remaining equations can be reduced to one by placing hinges at the abutments. This is the case used by the authors in testing the central rib. The very narrow skewed arch acts the same as a right arch with a span of the skewed length.

---

[11] "An Analysis of Multiple-Skew Arches on Elastic Piers," by J. Charles Rathbun, *Transactions* Am. Soc. C. E., Vol. 98 (1933), pp. 26–31.

[12] *Proceedings*, Am. Soc. C. E. (Society Affairs), March, 1926, p. 142.

[13] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1573.

Returning to the six equations of the skewed arch, assume a system of coordinates with the origin at the crown. The crown section is taken parallel to the abutment and radial (vertical for symmetrical arches). The x-axis is taken perpendicular to this section, the y-axis is vertical (radial), and the z-axis is perpendicular to these two, and, therefore, is horizontal and in the crown section. The general solution requires the finding of the forces in the direction of these coordinates and the moments about them and requires six equations.

If the arch is symmetrical about the two vertical planes through the y-axis, the one through the z-axis and the other through the center line of the upper roadway (the usual case), and, in addition, if the loads are also symmetrical about these planes, the crown force in the direction of the vertical axis and the moment about this axis both become zero. At the same time two equations disappear, and four equations and four unknowns remain. Next make the rather questionable assumption that the thrust at the crown and the horizontal shear at the crown are in the same ratio to each other as the tangent of the angle of skew—in this case, 35° (the complement of the 55° given by the authors). Also assume that the moments about these axes, the z-axis and the x-axis, are in this same ratio. The problem is now reduced to two unknowns and two equations, and the force line follows the central arch rib. If the abutments are designed as hinges, this reduces the problem to one equation in one unknown (which is the case assumed by the authors), and the formula is as given by Eq. 1.

The two assumptions involving the ratios of the crown forces and moments are fulfilled only under certain conditions, the most important being that the arch and loads must be placed symmetrically about the two vertical planes through the crown indicated previously. The test loads all fulfilled these conditions. In addition, the shortening of the arch rib, and its deformation due to shear, must be neglected. Another necessary condition is that the abutments do not rotate. Unfortunately, the rotation of these abutments was not measured, but from the results obtained the rotation must have been small and in a direction that tended to correct the other effects. Another assumption involved in the loading is that the earth-fill pressure is parallel to the direction of the upper roadway. This pressure is questionable in its nature. The usual assumption is that the pressure is perpendicular to the abutment face and therefore contributes to skew action.

It is to be noted that the readings given are all on the central rib where any skew effect would be a minimum. The readings on the outside girder are not given in the paper, but the authors indicate that some skew effect exists. The slab joining the several ribs evidently has sufficient rigidity to produce this effect. The torsional stresses in the slabs due to the complicated crown section are difficult to evaluate or observe; those due to horizontal shear are not so difficult. Observations on the slabs might show interesting results. Of course, these stresses are not dangerous because, if they are beyond the allowable limit, adjustment will take place since the slab is not a vital part of the arch system. If they had been made with shear joints or expansion joints (as was done on a skew arch bridge in Tacoma, Wash., with disastrous results),[14] the structure would still have acted as anticipated, but probably with no skew effect.

The writer feels that the objects of making the tests (see "Extensometer Tests: Object") have not all been obtained. For example (Object (1)), the true stress conditions at the questionable places have not been measured. The central arch rib will follow the approximate theory; but will the slab or the outer ribs follow this theory under skew loading? Failure to measure the abutment rotation prevents a check by the theory of the skew arch ring. Unless the authors refer to their "elastic theory," a comparison of true and theoretical stresses has not been made except to a very limited degree. It is to be noted that no effects of skew have been given (Object (2)). This effect is the important and dangerous condition in a skew arch. The elastic action of the system has been studied to a very limited degree only (Object (3)). The data secured (Object (4)) is valuable and adds one more test to the verification of the theory of the skew arch. That no observations were made on the rotation of the hinges detracts very much from its value, however.

The idea of cutting a bar and noting its change of length in the unstrained condition requires considerable caution in its use. It assumes that the bar has been placed in the structure in an unstrained condition, which assumption is far from the truth. For example, assume a 1-in. bar which, due to normal handling, is slightly bent with a radius of curvature of 1,200 ft. When laid in the forms, it is forced into line and wired, but it has a bending stress of 1,000 lb per sq in. If measurements are taken on one side of this bar only, after which the bar is released, there may be an error of 1,000 lb per sq in. in the steel measurement and a corresponding error in the concrete. This error cannot be detected by observing the bar and noting if it straightens up when released because, assuming the foregoing values in a 10-in. gage length, the deflection from a straight line is only $\frac{1}{600}$ in., which is too small for field measurements. If the radius were taken as 120 ft and the deflection as $\frac{1}{60}$ in., the condition would not be unusual and the error could be 10,000 lb per sq in. for the steel. Therefore, it becomes necessary to take measurements on opposite sides of the bar. This involves a great deal of concrete chipping, unless the gage is constructed for this type of observation. The authors should clarify this point. The cutting and resplicing of the stressed bars cause a redistribution of stress among the several bars of the bridge that might be objectionable to the owners but do not affect the validity of the observation. This "cut-bar" method has been suggested several times in the writer's experience but was rejected for the aforementioned reasons.

---

[14] *Engineering News-Record*, February 22, 1923.

An alternate method (which has not been used to the writer's knowledge) is to take a small bar (the diameter being governed by its slenderness ratio when acting as a column), suspend it on two supports so adjusted that the effect of bending moment is zero over the gage lengths, and embed this bar in the concrete at the point to be measured. The gage points are placed on the bar before embedment and are well greased. The distance between them is measured before and after embedment. This initially unstressed bar then can be measured for strain at any time, and finally it can be taken out and the gage length checked. The bar must be long enough to insure sufficient embedment on either side of the gage points. Even in this case gage points on opposite sides of the bar are desirable.

The authors are incorrect in their remark that few measurements have been taken on structures in service where the extensometer has been used. The writer can recall several without taking the trouble to make a bibliography. Although the point is of little value, since the question has been raised it might be of interest to see such a bibliography on the subject. It would include the field observations and extensometer measurements by Clyde T. Morris and also by S. C. Hollister, Members, Am. Soc. C. E. The Progress Report of the Committee on Concrete and Reinforced Concrete Arches, dated January 20, 1926, contains more than ten references to field measurement projects.

The bibliography of this paper appears to be one on the use of the strain gage, supplemented by a few standard works on structural analysis and a few references on impact. The important phase of the paper, the stresses in a skew arch, is not touched in this bibliography, although several papers have been written on this subject between the dates given by the author (1917 to 1941), and these papers include strain measurements on existing structures. The title of the list should be less inclusive or a number of papers on the skew arch should be included, preferably the latter because literature on this subject apparently needs to be brought more to the attention of the profession.

The writer wishes to comment on the authors' conclusions as follows:

(4) The low magnitude of temperature stresses in the structure is probably due to the fact that the abutments moved horizontally with the expansion and contraction of the arch due to temperature changes, thus tending to annul the stresses.

(6) That the arch ring follows the approximate method of skew arch analysis has been proved for the central girder only.

(7) The reasons why the basic design assumptions have not been verified have been explained at length.

(9) That the arch follows the authors' "elastic theory" has not been shown except for the central girder. They neglect the stresses due to skew which have not been touched upon in the paper. This is a very dangerous and incorrect conclusion.

(10) and (11) The conclusion that there is lateral distribution of load is correct. It is this lateral distribution through the slab that makes the skew arch analysis a problem. The complex torsional condition resulting from the skew of the structure produces the dangerous stresses, if any. The remark

that "The objectives of this investigation did not embrace a study of this phase in the facia and outer frames" should be emphasized to the extent that, with one reading of the paper in order to secure data on the skew arch analysis, one will then realize that this paper is primarily one of testing and that the authors are not putting forth the idea that the approximate method of skew arch design applied to the two-hinged skew arch has proved satisfactory. It is a dangerous method and could have been unsatisfactory had the hinges acted as designed.

(15) These tests definitely do not warrant the conclusion that the approximate theory (the authors' elastic theory) is correct for hinged skew arches; nor do the tests prove that the theory is incorrect.

(17) The conclusion that the central girder functions as a simple arch is approximately correct, theoretically, if the abutments do not rotate. The other girders will also function in this manner under certain definite conditions of loading.

(18) The data from which this conclusion was drawn are of value, and it is hoped that they will be published in the closure.

(20) In the "cut-bar" technique the authors should show how they avoided stresses due to bending the bar. If they measured both sides of the bar to secure the average strain in the center, this might well be mentioned as a warning to those who use the method in the future.

The writer is very much impressed with this paper from several angles. The method in which the obtuse abutments carried most of the load (which antedates the modern theory) has not been used, and seems at last to have been abandoned in skew arch analysis. The more simple method of using the skew arch and treating it as a right arch is nearer the truth if the hinges do not exist or act.

Although this paper by title and synopsis is one on stress measurement, it actually is one on checking the method of analysis of an arch with a 35° skew. The writer feels strongly that the work performed by the Society's Committee on Concrete and Reinforced Concrete Arches, and the several papers published by the Society, should have been considered more carefully before the measurements were taken, and that the literature on skew arches should have been given a place in the bibliography. If this had been done, the stresses in the structure as a skew arch might have been given more weight in the paper.

In closing, the writer wishes to urge that designers of the skew concrete arches investigate carefully and read the literature on the stresses due to skew. A statically indeterminate structure with six redundants is comparatively safe; but should not the stresses induced by loads be analyzed carefully so that a lack of understanding of the problem may not outweigh the factor of safety? It is hoped that this paper will revive an interest in the skew arch problem and that this structure will obtain the popularity it deserves.

THEODORE BELZNER,[15] **AFFILIATE AM. SOC. C. E.**—The statement made by the authors that few measurements of stresses on structures in service had been taken until about 1917 is incorrect. Many strain-gage measurements in actual construction or maintenance work on bridges prior to that period had been made. The writer firmly believes that a complete bibliography on this subject should be brought substantially up to date.

---

[15] Insp. of Steel and Bridge Insp. in Chg., Brooklyn Bridge, Dept. of Public Works, City of New York, Brooklyn, N. Y.

One case in particular, in a bridge of large span, is the Williamsburg Bridge across the East River in New York, N. Y., not given in the Appendix. Prior to 1917, stresses were measured on the Williamsburg Bridge during the summer of 1911; they were measured under train movements; also, during 1913 and 1914, when a comprehensive series of extensometer investigations were made in connection with the strengthening of the end spans of this bridge. This work was done[16] by the Department of Bridges (later the Department of Plant and Structures, and finally Department of Public Works), City of New York, in cooperation with the National Bureau of Standards, under the auspices of the late James E. Howard, engineer physicist, on the important truss members at the main towers and legs of the Brooklyn intermediate towers.

The precision attained with the Howard extensometer used in this test proved to be an invaluable aid, and its merits were illustrated in certain vital operations, especially with the various stages of wedging, and in the transferring of stresses from the old to the new diagonal members of the end trusses.

The writer agrees with the authors that field stress measurements "require a high order of instrumental and technical skill in order to be of value." The skill required to obtain reliable results in strain-gage measurements is not in the possession of all. In other words, the most important objective to be considered in taking stress-strain measurements (other factors being equal) is to obtain consistent results; and, in order to secure such results (which are absolutely essential), persistent patience and painstaking thoroughness, combined with good judgment on the part of the observer, are required, until he experiences little or no difficulty. It is upon the observer that the value of such measurements will depend.

SALTS IN IRRIGATION WATER

BY RAYMOND A. HILL,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. S. SCOFIELD, HERMAN STABLER, M. R. LEWIS, LOUIS J. ALEXANDER, W. D. COLLINS, JOHN H. BLISS, AND RAYMOND A. HILL.

SYNOPSIS

Those concerned with domestic and industrial water supplies were the first to appreciate the importance of the mineral salts invariably present in natural stream and ground waters. Irrigation engineers later began to realize that water in its pure form is never found in nature, and that natural water may be properly termed a mineral, of which H_2O is the principal constituent.

Unfortunately, there has been a tendency for irrigation engineers to disregard the character of the other constituents of natural water, limiting themselves largely to consideration of the total amount of dissolved solids. The interpretation of chemical analyses of irrigation water generally has been left to the agriculturalist. In an effort to bridge this gap between the engineer and the agriculturalist, the writer developed a geochemical chart. This he has found most useful for the classification of irrigation waters and for the solution of problems having to do with mixtures of water and with changes in quality resulting from the use of water for irrigation.

GEOCHEMICAL CLASSIFICATIONS

In 1911 Chase Palmer presented[2] a method for geochemical classification of natural waters. In his description he stated:

> "Nearly all terrestrial waters have two general properties, salinity and alkalinity, on whose relative proportions their fundamental characters depend. Salinity is caused by salts that are not hydrolyzed; alkalinity is attributed to free alkaline bases produced by the hydrolytic action of water on solutions of bicarbonates and on solutions of salts of other weak acids.
>
> "All the positive radicals, including hydrogen, may participate in producing salinity; but of the negative radicals only those of the actively strong acids can perform a similar function. The principal strong acids in natural waters are represented by the sulphates, chlorides, and nitrates."

NOTE.—Published in June, 1941, *Proceedings*.

[1] Cons. Engr. (Leeds, Hill, Barnard & Jewett), Los Angeles, Calif.

[2] "The Geochemical Interpretation of Water Analyses," by Chase Palmer, *Bulletin No. 479*, U. S. Geological Survey, 1911.

In accordance with the prevalence of the reacting values of the groups of positive radicals in the system, five special properties are possible, according to Mr. Palmer—namely, (1) primary salinity (alkali salinity); (2) primary alkalinity (permanent alkalinity); (3) secondary salinity (permanent hardness); (4) secondary alkalinity (temporary alkalinity); and (5) tertiary salinity (acidity). He made the following statement with reference to these five special properties:

> "The character of natural waters with reference to the lithology of the region from which they are derived, to their solvent action on minerals with which they may come in contact, to sedimentary deposits that they are likely to form, to their effect on industrial processes, and to their chemical action in general can best be portrayed by a statement of as many of the five special properties * * * as may be found, expressed in percentages of their totality."

In any system of geochemical classification it is necessary that the reacting values be used—that is, the equivalent weights of hydrogen, usually expressed as milligram equivalents of hydrogen per liter. Substantially, 1 mg of hydrogen per liter is 1 ppm of hydrogen; consequently, "milligrams equivalent per liter" can be termed "equivalents per million," abbreviated to "epm." The equivalent weights of the more common ions are as follows:

Calcium (Ca), 20.04	Carbonate (CO_3), 30.00
Magnesium (Mg), 12.16	Bicarbonate (H CO_3), 61.01
Sodium (Na), 23.00	Sulfate (SO_4), 48.03
Potassium (K), 39.10	Chloride (Cl), 35.46
Nitrate (NO_3), 62.02	

Mr. Palmer computed the percentage reacting values of each ion from the ratio of the equivalent weight of that ion to the equivalent weight of all of the ions. However, because half of the ions are positive and half are negative, it is now more usual to express the percentage reacting value of any positive ion as the ratio of the equivalent weight of that ion to the total equivalent weight of all cations. Likewise, it is customary to compute the equivalent weight of any negative ion, such as the sulfate radical, as the ratio of the equivalent weight of SO_4 to the total equivalent weight of all anions. Regardless of the manner of computing the individual percentage reacting values, the geochemical groups are reported as percentages which themselves total 100%.

Tertiary salinity, as classified by Mr. Palmer, is rarely found in irrigation waters. The magnitude of the other four geochemical classifications suggested by him can be computed by grouping the ions normally present in natural waters in the following manner:

Primary Salinity.—Maximum grouping of Na, K, SO_4, Cl, and NO_3 ions—that is, the greatest possible amount of sodium sulfate, sodium chloride, sodium nitrate, potassium sulfate, potassium chloride, and potassium nitrate that could be in the solution.

Primary Alkalinity.—Minimum grouping of Na, K, H CO_3, and CO_3 ions—that is, the smallest possible amount of sodium bicarbonate and carbonate, and of potassium bicarbonate and carbonate, which could be in the solution.

Secondary Salinity.—Minimum grouping of Ca, Mg, SO_4, Cl, and NO_3 ions—that is, the smallest possible amount of calcium sulfate, calcium chloride, calcium nitrate, magnesium sulfate, magnesium chloride, and magnesium nitrate which could be in the solution.

Secondary Alkalinity.—Maximum grouping of Ca, Mg, $H\,CO_3$, and CO_3 ions—that is, the greatest possible amount of calcium bicarbonate and carbonate and of magnesium bicarbonate and carbonate that could be in the solution.

This system of geochemical classification was particularly adapted to the study of waters used for domestic and industrial purposes. For the interpretation of analyses of water used in agriculture it was felt desirable to group the sulfates with the carbonates rather than with the chlorides and nitrates. This resulted in the following four geochemical groups of salts that can be used to classify all but definitely acid waters:

Z_1.—Maximum grouping of Na, K, Cl, and NO_3 ions—that is, the greatest possible amount of sodium chloride, sodium nitrate, potassium chloride, and potassium nitrate that could be in the solution.

Z_2.—Minimum grouping of Na, K, SO_4, $H\,CO_3$, and CO_3 ions—that is, the smallest possible amount of sodium sulfate, sodium bicarbonate and carbonate, potassium sulfate, and potassium bicarbonate and carbonate that could be in the solution.

Z_3.—Minimum grouping of Ca, Mg, Cl, and NO_3 ions—that is, the smallest possible amount of calcium chloride, calcium nitrate, magnesium chloride, and magnesium nitrate that could be in the solution.

Z_4.—Maximum grouping of Ca, Mg, SO_4, $H\,CO_3$, and CO_3 ions—that is, the greatest possible amount of calcium sulfate, calcium bicarbonate and carbonate, magnesium sulfate, and magnesium bicarbonate and carbonate that could be in the solution.

The designations Z_1, Z_2, Z_3, and Z_4 were used rather than names to avoid confusion with the classification suggested by Mr. Palmer. Group Z_1 is composed largely of sodium chloride; hence it is termed the Common Salt Group. The second group includes those salts commonly called "white alkali" and "black alkali," and this might be called the Alkali Group. Group Z_3 is sometimes referred to as the Bittern Group. Group Z_4 is termed the Hardness Group because it is made up of those salts which most frequently produce hardness in water.

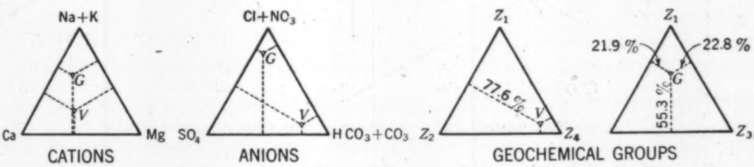
Development of Geochemical Chart

From the nature of the geochemical groups, as defined, there never can be more than three in any sample of water. Of these, Group Z_1 is almost always present, as is Group Z_4, but it is not possible to have salts of both Group Z_2 and Group Z_3 in the solution. Usually, the equivalent weight of sodium and potassium exceeds the amount of chlorides and nitrates. In such event, all of the latter are assigned to Group Z_1; should the amount of chlorides exceed the amount of the alkali bases, all of the sodium and potassium would be included in Group Z_1; in either case, nothing remains to form the fourth group.

The sum of the percentage values of the three groups present being equal to unity, the geochemical character of any water can be represented by a point within an equilateral triangle located so that the perpendiculars to that point are proportional to these percentages. A similar method of plotting can be used to show the relative proportion of the principal ions found in natural water, because there are usually only three cations present in substantial quantities, and likewise the sulfate, bicarbonate, and chloride ions usually constitute almost all of the anions. However, because of the limitation on the number of variables that can be plotted in this manner, it is necessary to combine the percentages of potassium and sodium, and to lump carbonates with bicarbonates, and nitrates with chlorides.

Typical plottings of two waters, the analyses of these waters, and the computation of the geochemical groups are shown in Table 1. The points marked "*V*" represent a sample of the Verde River below Bartlett Dam in Arizona. This water is generally characteristic of natural streams. The points marked "*G*" are for return flow in the Gila River in Arizona immediately above its confluence with the Salt River. The method of plotting is illustrated by the diagram showing the proportions of the various geochemical groups found in the Gila River water. If all of the salts were sodium chloride, the point would have fallen at the Z_1 vertex. Actually, 55.3% of the salts were of the Z_1 Group, and the plotted position is therefore 55.3% of the distance from the base opposite the Z_1 vertex toward that vertex of the equilateral triangle. Likewise, the plotted position is 22.8% of the distance from the base opposite the Z_4 vertex toward that vertex, and 21.9% toward the Z_3 vertex from the

TABLE 1.—ILLUSTRATIVE ANALYSIS, TRILINEAR PLOTTING OF CHEMICAL ANALYSES



Line	Unit	Cations			Σ	Anions			Groups

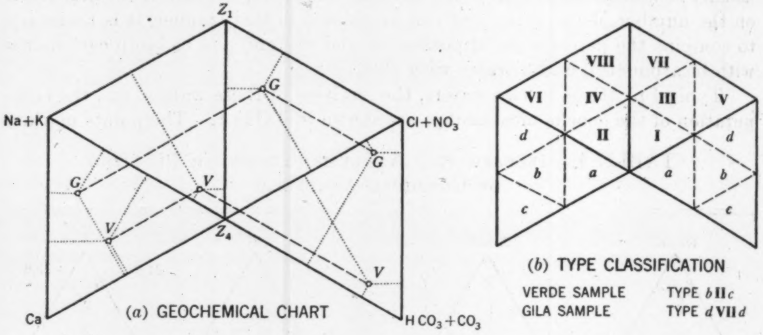
opposite base. The positions of the points V and G on the cation triangle and on the anion triangle were determined in the same manner by plotting the percentage reacting values of the respective ions.

Although the chemical character of almost any natural water could be illustrated thus by the use of four equilateral triangles, the same data can be shown more effectively on a chart that combines these four triangles in the manner shown in Fig. 1.



(*a*) GEOCHEMICAL CHART

(*b*) TYPE CLASSIFICATION

VERDE SAMPLE TYPE *b*II*c*
GILA SAMPLE TYPE *d*VII*d*

FIG. 1.—TRILINEAR PLOTTING OF ANALYSES ON GEOCHEMICAL CHART

Each of the triangles used for plotting the geochemical groups (Fig. 1(*a*)) has a Z_1 vertex and a Z_4 vertex; in other words, the $Z_1 - Z_4$ base is common to both. Consequently, by superimposing these vertexes a diamond is formed, the bisector of which is the common base. The lower sides of the diamond can now be treated as oblique coordinates, with the origin at the Z_4 vertex, reading in percentage of chloride to the right and percentage of sodium to the left.

By definition, a point plotted at the Z_4 vertex would represent a water containing neither sodium nor chloride, whereas a point plotted along the side of the diamond connecting the Z_2 vertex and the Z_1 vertex would represent a water in which all salts were those of sodium and potassium. Similarly, a point on the line connecting the Z_3 with the Z_1 vertex of the diamond would indicate that all the salts were chlorides or nitrates. A point plotted on the cation triangle at the sodium vertex represents a water in which all of the positive ions are those of sodium and potassium, and a point along the opposite base would be for a water in which there was no sodium or potassium. Therefore, by bringing the cation triangle into contact with the diamond so that the sodium vertex of the cation triangle is coincident with the Z_2 vertex of the diamond and the magnesium vertex of the cation triangle is coincident with the Z_4 vertex of the diamond, a common scale of sodium percentages can be used. In like manner, the anion triangle can be placed beside the diamond with the chloride and nitrate vertex coincident with the Z_3 vertex of the diamond and with the sulfate vertex coincident with the Z_4 vertex of the diamond. When this is done, a common scale of chlorides plus nitrates can be used for the anion triangle and for the geochemical groups.

In Fig. 1 are shown the same points as those in Table 1 for samples of water from the Verde River and the Gila River in Arizona. It will be noted that the points in the cation triangle and those in the anion triangle can be projected parallel to the coordinate axes to intersections that coincide with the points plotted in the diamond. In fact, in the actual use of the geochemical chart it is customary to plot the points representing the water in the cation triangle and in the anion triangle from the percentage reacting values of the ions, and then to plot the percentage of sodium plus potassium against the percentage of chloride plus nitrate, using the sides of the diamond as oblique coordinates, only checking the position of the point by computation of the Z_2 or Z_3 perpendicular, as the case may be.

Types of Water

Waters of different chemical characteristics can be classified readily from their plotted positions on the geochemical chart. When lines are drawn parallel to each base at 50% of the distance toward the opposite vertex, each of the four fundamental triangles is divided into four secondary triangles. These have been numbered arbitrarily in the manner shown in Fig. 1(*b*), following a pattern that can be remembered easily. The sample of water from the Verde River is characteristic of many natural streams and would usually be referred to as Type II water. Were more precise description desirable, it would be termed a Type *b*II*c* water. The Roman numeral II indicates a water in which most of the salts fall in Group Z_4 and with some salts in Group Z_2 but none in Group Z_3. The prefix "*b*" indicates a water in which no one of the positive ions exceeds 50% of the total. The suffix "*c*" defines a water in which more than 50% of the anions are bicarbonates or carbonates. The sample from the Gila River is a Type VII water; for consistency, the prefix "*d*" and the suffix "*d*" could be added, although by the nature of the diagram any water of Type VII contains more than 50% sodium and more than 50% chloride. This water contains salts of Group Z_3, but ont of Group Z_2, and might well be called "irrigation sewage."

Eight primary types are thus available for cataloging irrigation waters, which can be broken down into thirty-two subtypes by use of letters indicating the preponderance of certain positive and negative ions. No attempt will be made herein to list these thirty-two different types of water in the order of their desirability for use in irrigation agriculture. Suffice it to state that, in the case of waters of equal concentration, those in Type II are preferable, and that those of Type VI should be avoided. It is hoped that some discusser will proceed further and describe the effect of different kinds of water on soils and on plant growth.

Mixtures of Different Waters

It can be demonstrated that the plotted position of a mixture of two waters must lie on a straight line connecting the plotted positions of each of the waters comprising the mixture. It can be demonstrated further that the distance of the plotted position of the mixture from either of the two waters making up the mixture depends directly upon the ratio between the total quantity of salts contributed by one water and that contributed by the other. When the respective products of the concentrations of salts in equivalents of hydrogen and the quantities of water are treated as forces normal to the plane of the paper, the position and magnitude of the mixture correspond to the resultant of the forces. Such products of concentration and quantity can be computed conveniently as equivalent tons of hydrogen, or tons-equivalent, abbreviated to "T_e." When the quantity of water is given in acre-feet, the quantity of any ion in tons-equivalent is equal to the quantity times the concentration in milligram equivalents of hydrogen per liter divided by 735, or algebraically:

$$T_e = \frac{C\,Q}{735} \qquad \text{(1)}$$

in which C is concentration of salts in equivalents per million; and Q is quantity of water in acre-feet.

When it is known that one water is in fact a true mixture of two or even three different waters, the amount of each contribution to the mixture can be computed analytically by use of simultaneous equations. However, when it is only suspected that one water is a mixture of several different waters, or when the amount and character of one of the contributing supplies is unknown, an analytical solution becomes impracticable.

The first step in the solution of such a problem is to determine whether or not the presumed mixture is in fact a mixture. This can be readily ascertained graphically by use of the geochemical chart. A typical solution for a true mixture of three waters is shown in Table 2; in this it is assumed that the amount of water from each source is unknown.

For purposes of illustration, the sample of Verde River water (*V*) and the sample of Gila River water (*G*) described in connection with Table 1 have been used. The third water (*H*) contributing to the presumed mixture is somewhat similar to ground waters found in the same region; in fact, the mixture (*M*) is quite representative of water being used for irrigation in the Gila River Valley west of Phoenix, Ariz. The known data are shown in Table 2 and are limited to the amount of water in the mixture and to analyses of samples of the mixture, of Verde River water, of Gila River water, and of the third water. It is to be noted that the total amount of salt in each water, expressed in equivalents per million and in tons-equivalent, is the sum of the positive ions, or the sum of the negative ions, but is not the sum of both.

In each of the three figures in Table 2 the point *M* falls within the triangle formed by connecting points *V*, *G*, and *H*. This indicates, but does not prove, that the water represented by points *M* is a mixture of the other three waters. If the presumed mixture *M* is in fact a mixture of all of the three, it can be considered as being made up of any one of the three and a mixture of the other two. Consequently, if a line is drawn from point *G*, for example, through the point *M* to its intersection with the line *HV* at point *c*, the latter point represents a mixture of water *V* and water *H* in the same proportion as these two occur in the mixture of all three waters. The projection of point *c* in the cation triangle, therefore, must interest the projection of point *c* in the anion triangle at point *c* within the geochemical diamond. The same is necessarily true for points *a* and *b*, determined by drawing lines from the plotted positions of water *H* and water *V* through the plotted positions of the mixture.

12	%	27.7	23.8	48.5	100.0	30.6	24.1	45.3

[a] Computed values shown in parentheses.

When it has been determined that the presumed mixture is in fact a true mixture, the salt, in tons-equivalent, contributed by each of the three waters comprising the mixture can be computed, with an accuracy commensurate with that of the analyses themselves, by measuring, at some convenient scale, the distance from point M to each of the aforementioned points, and by treating these distances as lever arms of forces normal to the plane of the paper. For example, if moments are taken about the line HG;

$$\begin{aligned}(84 + 32)\ V &= 32\ M\\ 116\ V &= 32 \times 47.62\\ V &= 13.21\end{aligned}$$

In the foregoing, 47.62 is the number of tons-equivalent in the mixture, so that 13.21 is the number of tons-equivalent in the Verde River water contributing to that mixture. The difference (that is, 34.41 T_e) represents the tons-equivalent of salts contributed by the Gila River water and by the hypothetical water, in such a proportion that the mixture of these two alone would plot at point b. In similar manner, the tons-equivalent of salt contributed by each of these waters is determined. Knowing the total amount of salt in each water making up the mixture, and the concentration of salt in samples of each, the number of acre-feet of water from each source can then be computed directly by multiplying the tons-equivalent by 735 and by dividing the product by the concentration in equivalents per million. For example, in the case of the Verde River water, the concentration was 5.40 epm and the total amount of salts was 13.21 T_e; hence, the Verde River contributed 1,800 acre-ft of water to the mixture. From the other data shown in Table 2, it was found that the Gila River furnished 300 acre-ft, and that the remaining 900 acre-ft were from the hypothetical well.

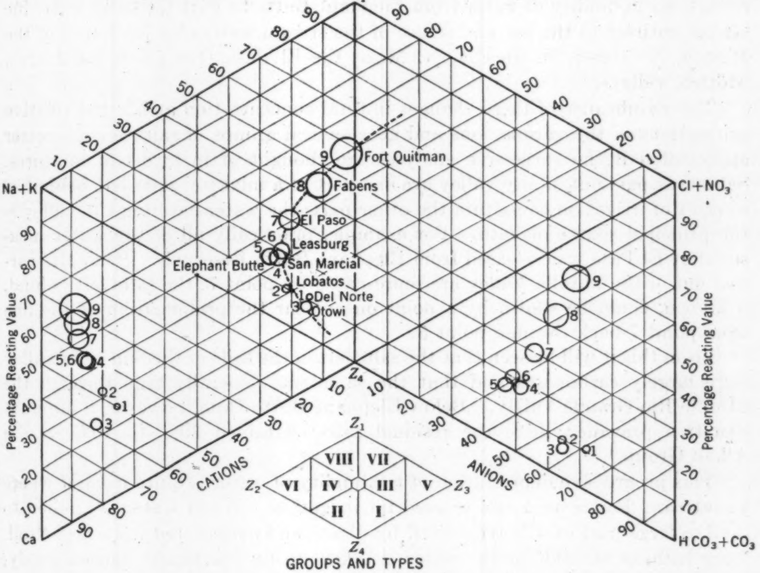
CHANGES IN QUALITY

The foregoing has been descriptive of the manner in which the geochemical chart was developed and of the fundamental principles involved in its use. One of the many applications to which the chart can be put is that shown in Table 3. On the graph have been plotted characteristic analyses of samples taken from the Rio Grande at various stations along its course from the mountains in Colorado to Fort Quitman, Tex. The data are from the 1936 report of the Rio Grande Joint Investigation. The chart itself is a reduction of a standard commercial form originally printed with 2% graduations at a scale of about 1 in. equals 20%. The weighted average concentration of the ions in equivalents per million is also given in Table 3.

As an aid in visualization of the changes that occur in the quality of the waters of the Rio Grande along its course, the analyses have been indicated by circles whose areas are proportional to the concentration of salts, ranging from the small circle representing samples from the Rio Grande at Del Norte, Colo., to the large circle corresponding to the highly concentrated waters found in the Rio Grande at Fort Quitman.

It is to be noted from the plotting of these data that the water coming out of the mountains is of Type *cIIc*—that is, a water in which calcium bicarbonate predominates. Below Del Norte lies the San Luis Valley in Colorado within which there are several hundred thousand acres of irrigated land. The change in quality resulting from irrigation use is reflected by the shift from point 1 to point 2, the latter being for the Lobatos station near the Colorado-New Mexico boundary. Below this station there are other tributary streams, particularly Rio Chama, draining the high mountains in northern New Mexico. Some of these waters obviously contain more of the Z_4 Group of salts than does the water of the Rio Grande at Del Norte, because the analysis for Otowi, N. Mex. (point 3), plots between the Z_4 vertex and point 2 and closer to that vertex than the Del Norte water.

TABLE 3.—GEOCHEMICAL CLASSIFICATION OF THE WATER OF THE RIO GRANDE ABOVE FORT QUITMAN, TEX.



No.	Location	Ca	Mg	Na + K	Total anions	CO_3 + HCO_3	SO_4	Cl + NO_3
1	Del Norte, Colo.	0.56	0.27	0.30	1.14	0.70	0.32	0.12
2	Lobatos, Colo.	1.39	0.58	0.91	2.83	1.54	1.00	0.29

5	Elephant Butte, N. Mex.	3.75	1.28	3.88	8.96	2.66	4.76	1.54
6	Leasburg, N. Mex.	4.05	1.35	4.20	9.63	2.82	4.88	1.93
7	El Paso, Tex.	4.95	1.70	6.98	13.65	3.55	6.07	4.03
8	Fabens, Tex.	6.90	2.75	12.40	22.12	4.10	8.26	9.76
9	Fort Quitman, Tex.	9.54	3.75	19.78	33.20	4.01	10.17	19.02

Below Otowi, which is northwest of Santa Fe, N. Mex., there is the Middle Rio Grande Valley which extends along the river to San Marcial, N. Mex., near the head of Elephant Butte Reservoir. The marked reduction in quality that occurs between Otowi and San Marcial is perhaps due most to the influence of tributary streams, such as Rio Puerco, draining the plateaus of western New Mexico. The water released from Elephant Butte (point 5) differs somewhat from the inflow at San Marcial because the supply drawn out of the reservoir in 1936 included water that came into the reservoir in the preceding year. The reductions in quality of water from Elephant Butte to Fort Quitman were due almost entirely to the use and re-use of the stream waters for irrigation of the Rincon, N. Mex.; the Mesilla, N. Mex.; the El Paso, Tex.; and the Juarez, Mexico, valleys.

The significance of these changes in total concentration and in the relative proportions of the various ions and geochemical groups of salts will be better appreciated if the successive analyses are thought of in terms of mixtures. Salts that pass out of any valley are one part of a mixture; salts left behind as a result of irrigation constitute the other part; the water entering the valley is the principal source of both. For example, practically all of the water measured at El Paso was released from Elephant Butte Reservoir. The salts carried out of the Mesilla Valley are represented by point 7; the salts left behind, if known, could be shown by a point on or near the prolongation of the line from point 7 back through point 5.

From this it will be seen that the salts left in the soils of the San Luis Valley were largely carbonates and that the same was generally true through the Middle Rio Grande Valley. Below Elephant Butte Dam, however, a different situation prevailed; here the residual salts contained 30% to 40% of the Alkali Group.

This progressive depreciation of the quality of water is quite natural where the stream flow is used and re-used for irrigation. When water is applied to land, a large part of it is transpired by plants and evaporated from moist soil. Very little of the salt in the water is taken up by the plants; consequently, there is a much greater concentration of salts in the soil solution than in the irrigation supply. Since the carbonates of calcium and magnesium are sparingly soluble, they are precipitated first. The irrigation percolate, which finds its way back into the river either through drains or by natural seepage, thus contains a higher proportion of sulfates, chlorides, and sodium than the waters that were diverted for irrigation. Progressively downstream, H_2O is lost to the atmosphere by evaporation and the less soluble salts are left behind by precipitation, until only irrigation sewage remains.
